D = p-well (“tub”) structure; contains NMOS transistors.
E = p-type “channel stop” for p-well; intra-well (E) and inter-well (E') field isolation.
F = PMOS source/drain; basic transistor structure.
G = PMOS buried-channel threshold voltage adjust; sets p-channel V_t (or V_p).
H = PMOS “punchthrough” suppression.
I = n-well (“tub”) structure; contains PMOS transistors.
J = n-type “channel stop” for n-well; intra-well (J) and inter-well (J') field isolation.
K = NMOS “punchthrough” suppression.
L = PMOS LDD; hot carrier suppresion.
M = polysilicon gate doping (typically n+); improves conductance.

Another ion beam process for semiconductor fabrication is the silicon-on-insulator (SOI) technology. By means of ion implantation at large dose, it is possible to create a silicon layer on top of an insulating silicon oxide layer. Another possibility is a combination of ion implantation and wafer bonding. The surface of a wafer is oxidized. Then hydrogen is implanted through the oxide and a defect layer is formed. Another wafer is bonded to the implanted one. The latter is cut along the defect plane (smart cut process) by means of a heat treatment, forming a new surface of silicon on silicon oxide which is annealed and polished. Thus, a monocrystalline silicon layer on an insulator is fabricated. The SOI material is

dedicated to low-voltage, low-power, high speed systems.

Detailed information on such applications for semiconductors may be found in many monographs [13], [14], articles [16] and the proceedings of the international conferences on, e.g., Ion Beam Modification of Materials (IBMM) and Ion Implantation Technology (IIT).

4.2. Metal Modification

Ion beam modification of metals began in the mid-1970s, mainly for improving wear and corrosion performance. Advantages were seen in the low temperature and the nonequilibrium nature of the process. The conventional metallurgical solubility limits could be exceeded with the possibility to create materials with improved properties.

In contrast to semiconductor processing, ion beam modification of metals has so far only found limited industrial application. The main obstacle for this is the high cost of ion beam treatment. In contrast to most applications in semiconductor processing, metal treatment requires high implantation doses. Additionally, ion beam treatment is in competition with other techniques such as galvanic deposition, and chemical or physical vapor deposition, which yield larger depths of modification or coating. In the following, a number of examples for modification of metals with ion beams will be given.

Nitriding. The certainly most widely investigated application of ion beam treatment of metals is nitriding by nitrogen ion implantation for increased wear life [17-22] (⟶ Metals, Surface Treatment – Nitriding and Nitrocarburizing Methods). The implantation doses typically range from 1 to 8×10^{17} N ions/cm^2, the ion energies from 50 to 100 keV. In general, nitrogen ion implantation leads to hardening. This may be due to different effects, the most important ones being pinning of dislocations, and precipitation of hard phases. In general, nitrides are hard and increase the hardness of the metal in the near-surface zone which, in turn, reduces wear. With ion implantation, nitriding may be performed at room temperature which allows to treat temperature-sensitive metals. Typically, the temperatures can be held below 200 °C. At such temperatures, no phase changes or segregations occur. No distortion of the workpiece is expected, neither does it change its dimensions. Additionally, the surface finish is almost unchanged. Since no coating is applied, there is no adhesive failure to be expected, even at high loads.

Nitriding has been carried out with a large number of alloys, including steels such as austenitic stainless steels and high speed steels, aluminum alloys, titanium alloys such as Ti6Al4V, alloys of other transition metals, including chromium, molybdenum, and tantalum, and hard metals such as tungsten carbide. The implanted nitrogen doses ranged from 10^{17} to 10^{18} N ions/cm^2.

Wear tests under different conditions showed that despite the shallowness of the nitrided zone (well below 1 µm) good results were obtained (see Table 1). This lead to several industrial applications, e.g., in the USA in biomedical applications, where endoprostheses were commercially treated [17], [18]; or in Denmark, where tools for, e.g., plastics processing were modified [19], [20], [24]. Reports on application-oriented studies from other countries such as China, Japan, and Spain may be found in [20], [22], [25-27]. Ion beam processing of tools has been focused on precision tools to avoid alterations in the dimensions or shape by coating or by heating; tools with a refined finish, i.e., highly polished tools; tools heat treated at low temperatures; and very expensive tools because the risk of negative effects in processing is small.

Table 1. Applications of ion implantation in order to increase wear life of tools [17-22]

Application	Life-time increase
Tools for piercing, stamping or punching metal	3–5 ×
e.g., manufacturing of beverage cans (punches)	5–10 ×
Transformation of plastics (moulds, nozzles, valves)	3–4 ×
e.g., extrusion dies for polymer fiber	3–4 ×
Blades for cutting food (vegetables, bread, meat)	4–5 ×
Blades for cutting paper, cardboards, rubber, and plastic	3–7 ×
e.g., blades for cutting synthetic fiber	6 ×
Drills for metal and polymers	2–3 ×
e.g., carbide twist drills for printed circuit boards	2–3 ×

So far, the modified zones have been quite shallow. Their thickness has mainly been governed by ballistic effects which determine the travel distance of the ion in the metal. When the sample temperature is increased, either by an external heating source or, more easily, by energy input via an intense ion beam, diffusion adds as a transport mechanism [28]. In this case, even low ion energies may be used. Energies around 1 keV at ion current densities of several miliamperes per square centimeter were applied. At temperatures of 400 °C, the range of the incorporated nitrogen in austenitic stainless steel has been found to increase by an order of magnitude or more, beyond 10 µm, thus yielding a greatly increased wear life. In the process, a metastable expanded austenite phase may form, another mechanism being the precipitation of CrN, depending on the temperature. The hard nitride phase increases wear resistance, however, it deteriorates the corrosion performance. By an appropriate selection of the process parameters, particularly the temperature, an optimum in wear and corrosion performance can be obtained.

Apart from nitrogen, carbon, oxygen, boron, and a number of metals (⟶ Steel – Vacuum Vapor Deposition) have been implanted for wear reduction.

Formation of Metastable Alloys. As mentioned initially, a particularly strong feature of ion implantation is that virtually any element can be incorporated into any solid. This means that apart from nitrogen any other metalloid and any metal can be implanted into any metallic target. In this way, a metal can be alloyed with any other metal even if they are not soluble in each other. Thus, metastable alloys can be formed. An example is the alloying of iron with mercury, lead, or gold.

Amorphization. The formation of metastable phases is not only possible from a chemical, but also from a structural point of view. Metals are well known for their crystallinity. Ion bombardment can be used to induce an instability in the crystalline structure of metals, thus leading to amorphization [29]. Accumulation of radiation damage may force a metal into a structure without long-range order. Glassy metals exhibit interesting properties, e.g., with respect to corrosion or magnetism (⟶ Metallic Glasses). In conventional techniques the glassy state is obtained by transferring the metal into the liquid state and quenching it by rapidly cooling (splat cooling) the melt on a spinning wheel. This yields ribbons or films of glassy metals. The structural disorder in the melt is frozen in to a maximum amount by using quenching rates as high as possible. When the temperature is far below the recrystallization temperature, the amorphous state will be stable due to a kinetic barrier. The interaction of energetic ions with matter does also yield high quenching rates and is therefore suitable for forming glassy metals. In general, ion irradiation needs large enough ions for creating the required radiation damage and low enough temperatures for preventing recrystallization. For fabricating thin films of amorphous metals, different methods can be used. When intermetallics, e.g., Al_2Au, AlMn, AlFe, Al_3Ti, $AuIn_2$, NiAl, NiZr, FeNd, FeCu, Ni_2Al_3, CuTi, or Zr_3Al, are irradiated at low temperatures with heavy rare gas ions, they accumulate radiation damage and eventually become glassy. Another possibility is to implant metalloids such as P or B which stabilize the glassy state. Rather than bombarding alloys with ions, also multilayers can be irradiated.

Films and Coatings by Ion Beam Mixing. In the case of ion implantation, the base material is always a component of the modified zone. If an alloy or compound of different materials is needed as coating, ion beam mixing can be used. The deposited film is modified by ion irradiation, either structurally or in addition chemically. Thus, a metal can be coated with another metal or a nonmetal which is converted by ion implantation into a compound, e.g., by depositing a chromium film on steel, and implanting nitrogen ions into the film, thus creating a chromium nitride coating. Apart from a chemical change, the microstructural changes induced by ion irradiation play an important role. Prior to ion irradiation the features of the coating are defined by the deposition process. Among these are, e.g., the grain size and the crystal orientation, or, as a result of the microstructure, the porosity and the state of stress. These features can be affected by ion irradiation. By a radiation induced lattice rearrangement, the crystal orientation may be altered. Ion irradiation usually induces a preferential crystallographic orientation. By grain boundary motion, often a change in grain size is observed. The stress state can be influenced. Microporosity, often a consequence of open grain boundaries, can be reduced. In this way, properties such as hardness or corrosion resistance can be influenced. Apart from the film itself its interface to the substrate will be modified when ions travel through it. Figure 13. shows a schematic representation. Chemical bonds will be broken and formed. Impurities can be “diluted”, a mixed zone can be created both by ballistic mixing and by radiation enhanced diffusion. Depending on the combination film-substrate-ion a phase can be generated (interphase). Interface stress can be reduced. These effects may influence important properties of the film-substrate system, such as its porosity or its ohmic resistance. The probably most important property is the adhesion between film and substrate. The above mentioned effects usually lead to substantial enhancement of adherence between the film and the metal substrate.

Figure 13. Ion beam mixing of a coating on a substrate, forming a transition zone (gradient) or an interface. Both may enhance adhesion.

As ion beam mixing is essentially also limited by the range of the ions, it suffers from similar restrictions with respect to thickness of the modified zone as ion implantation. For metal modification often thicker modified zones are needed, e.g., for corrosion protection. The problem with shallowness of the modified zone can be overcome when thin films are deposited from the vapor phase under simultaneous rather than postdeposition bombardment with energetic ions (IBAD). Simultaneous ion irradiation or implantation influences the film in a way similar to ion beam mixing. In situ ion bombardment is particularly powerful with respect to film densification, preferential crystallographic orientation, grain size and morphology, and stress [30-32]. Thin films usually suffer from stress, either due to a mismatch in the thermal expansion coefficient or intrinsic stress, which arises from defects, impurities etc. Often, the stress state of physical vapor deposited films is tensile. By means of simultaneous ion irradiation, it may be reduced or changed to compressive stress. Figure 14. shows a typical dependence of the stress state on the I/A-ratio. The stress state changes from tensile to compressive, with a state of zero stress in the transition. This allows to deposit films with low stress levels, thus enhancing adhesion.

Figure 14. General dependence of stress of thin IBAD films on the ion to atom arrival ratio (I/A)

IBAD coatings range in their thickness from 0.1 µm up to 10 µm with a typical thickness of 1 to 2 µm. The coatings can be divided in elemental or compound layers and in single layers (monolithic) and multilayers. Films of a single element consist mostly of metals such as Al or transition metals like Ti, Cr or Ta, nonmetals such as Si, B, or, mostly, carbon. The latter is

usually an amorphous material with varying ratio in sp^2/sp^3 hybridization, sometimes including hydrogen. Among the compound films, the nitrides play a major role. TiN, ZrN, CrN, TaN and other transition metal nitrides, AlN from the main group metals, and nonmetal nitrides, particularly Si_3N_4, CN_x, and BN, especially the hard metastable cubic modifications, have been deposited on many kinds of metal substrates. All these can comparatively easily be formed by evaporating the element and irradiating the growing film with nitrogen ions. Another group of compounds are the oxides, such as Al_2O_3, SiO_2, TiO_2, or Ta_2O_5. When the element is highly reactive, the film can be formed by nonmetal ion implantation and reactions of the growing film with gas from the atmosphere. In this case, both reactive ions (nitrogen or oxygen) or rare gas ions, mostly argon, can be used. The most important and typical examples of nitride and oxide films on metals formed by reactive ion beam assisted deposition are TiN and Al2O3. When the element is not reactive enough, particularly in case of the main group elements, the nitrogen or oxygen has to be incorporated by ion implantation. Here, the I/A ratio directly determines the composition. Examples are AlN, SiO_2, Si_3N_4 and BN. While the metallically bonded transition metal nitrides can be grown crystalline over a wide temperature range, the covalent oxides and nitrides of the main group elements tend to grow amorphous.

Microlaminates. When different materials are deposited in alternating order or the ion beam is modulated, *multilayers* can be formed. These exhibit often considerably better features then single films of either of the materials, such as enhanced elasticity and hardness. Particularly, their mechanical strength can be greatly improved. Such so-called microlaminates have a great stability both against crack initiation and propagation. A typical examples is the system Al-Al_2O_3. The microlaminate shows a much lower crack initiation and propagation probability than either of the monolithic layers.

Wear protection. Most of the nitrides and oxides mentioned above are harder than metals. Therefore, they may serve as protection against wear. The most prominent of the nitrides is certainly TiN. It may be deposited by evaporation of titanium either under nitrogen ion bombardment or under rare gas, usually Ar, irradiation in an atmosphere of backfilled nitrogen. Depending on the process parameters titanium nitride may have a broad range in composition and also in hardness. Both comparatively soft and ductile films may be obtained with hardness well below that of bulk TiN (20 GN/m^2), but also a quality with considerably larger hardness can be obtained, where the films usually have intrinsic compressive stress. Friction and wear tests of TiN films on different substrates, including stainless steel, aluminum alloys, but also tungsten carbide, gave reductions both in friction coefficient and wear. Figure 15. shows the dependence of hardness and wear life of TiN formed by reactive IBAD on the Ar^+/Ti arrival ratio.

Figure 15. Dependence of hardness (left scale) and wear life (right scale, given as number *n* of passes of the wear test) of TiN formed by reactive IBAD on the Ar^+/Ti arrival ratio [32]

Of particular interest is the group of (potentially) ultrahard materials, namely diamond-like carbon (DCL) and cubic boron nitride (c-BN). Both can be grown by ion beam assisted deposition. Thin DLC films are often comparatively elastic and exhibit particularly low friction coefficients. Cubic boron nitride films show similar features and may improve the tribological performance of metals. However, the process window is comparatively narrow, and the films suffer from large compressive stresses which may cause adhesion problems.

Lubricant Coatings. Apart from hard coatings, solid lubricants can be used. Molybdenum sulfide (MoS_2) grown either as monolithic film or as multilayer in combination with hard coatings such as B, B_4C, or BN, show very low friction coefficients.

Corrosion Resistant Alloys. Metals may easily be alloyed by ion implanting an alloying element which leads to a more corrosion resistant alloy [33], [34]. An example is the implantation of chromium into iron which, if the implantation concentration exceeds 12 at%, becomes corrosion resistant in neutral aqueous media similar to stainless steels. In the literature, a large number of examples of ion implantation into various metals and alloys, including alloys based on iron, aluminum, titanium, nickel, and others are described. The implanted species were all kinds of metals and nonmetals including noble metals such as platinum or palladium, and metalloids such as phosphorus and boron. The layers formed protect against uniform corrosion, localized corrosion such as pitting and crevice corrosion, and hydrogen embrittlement, which may occur when metals are exposed to water, acids, or salt brines. However, the effect is often not long-lasting because the modified zone below the surface is too shallow. When corrosion progresses, the thin modified zone may be consumed in a short time, ranging from a few days to weeks. For particular cases a long-term protection can be achieved. The cathodic protection offered by implanting catalytically active noble metals such as platinum is very effective for some metals with active/passive transition behavior. These metals such as titanium are protected by a native oxide which leads to passive corrosion with low dissolution rates. In aggressive environment, the oxide may be dissolved with the result that active corrosion with high rates starts. The noble metal shifts the potential into a region where the oxide film is recovered and the metal remains passive. When the implanted protective material itself is not consumed by corrosion, it may remain on the metal surface and exert a long-term protection effect. In this way, titanium can be protected against corrosion in mineral acids or salt brines, and tantalum can be protected against corrosion and hydrogen embrittlement in hot concentrated mineral acids.

When the implanted zones are too thin and/or the effect is not long-lasting, ion beam assisted deposition of thicker films may be applied. Usually, a coating more corrosion resistant than the base material is used. It may consist of nonmetals such as boron, silicon, or carbon, resistant metals such as noble metals, but also aluminum, titanium or tantalum, or nitrides, carbides and oxides. It turns out that the most important characteristics of corrosion-resistant thin films deposited under ion bombardment are low microporosity and high adhesion [34]. These features can be optimized by proper selection of the main deposition process parameters which are I/A ratio, ion energy, and ion incidence angle. In the

beginning of film growth, ion beam mixing effects lead to a strengthening of the interface and to enhanced adhesion. During film growth, ion bombardment increases the density of the film material and closes micropores. Often, the closing of pores is enhanced when an off-normal ion incidence angle is chosen.

Again, multilayer films may be more effective than monolithic films. Figure 16. shows the iron dissolution currents of an iron sample coated with a Ti/TiN multilayer sequence. The multilayers are less porous than the corresponding single films of either Ti or TiN. It can be assumed that monolithic films contain pores from the substrate through the film to the surface. TiN grows in columns parallel to the surface normal. Between the columns, more or less open channels may exist. In a multilayer film with a sequence of a cubic nitride and a hexagonal metal crystalline structure, such continuous open structures are less likely to form.

Figure 16. Critical current densities deduced from current-potential plots for Ti/TiN multilayers deposited by IBAD on steel vs numbers of potential cycles

(●) CK45 steel, (*) Ti, (+) TiN, (♦) Ti/TiN ratio: 100/25, (○) ratio: 100/50, (■) ratio: 100/100, (□) ratio: 50/100, (▲) ratio: 25/100 [36]

Not only aqueous corrosion, but also high temperature corrosion in gases can be reduced. Coatings such as Si3N4 are effective in reducing oxidation of metals such as Ni and Cr and metallic alloys.

Films with Special Electric and Magnetic Properties. Apart from mechanical and chemical features, electric and magnetic properties can be influenced. For metal films, a strong dependence of the electric resistivity on ion energy, I/A-ratio, and type of metal has been found [35]. Magnetic properties such as coercivity can be influenced and films with giant magnetoresistance can be formed.

4.3. Ion Beam Modification of Insulators

The effects of ion beams in insulators are somewhat different from those in metals because:

- The electronic stopping of ions causes much more changes in insulators than in metals.
- Insulators are mostly compounds, which means that the incoming ions interact with chemical bonds during slowing down.
- The bombardment of insulators with ions may cause strong charging of the samples, an effect which has to be taken into account during the experiment.

The application of ion beams for insulator modification can be grouped in two categories:

1. Ion implantation and ion bombardment.
2. Metallization and ion beam assisted coatings.

The most important materials treated in practice are different types of polymers, engineering ceramics, and glasses.

4.3.1. *Ion Implantation and Ion Bombardment*

Polymers. Most polymers are not very stable to radiation, which means that already moderate fluences of heavy energetic ions may partly destroy the polymer structure. Figure 17. indicates the chemical changes caused by the ions with increasing dose and the corresponding variations of properties. In the low dose range mainly properties such as solubility or wettability are affected, in the higher dose range — near the region where graphite is formed — also hardness, conductivity, and optical properties are modified.

Figure 17. Dose dependence of the chemical and physical properties of polymers and the corresponding structural changes

Generation of Local Conductivity. Many researchers tried to induce conductivity in polymers, because this is an interesting possibility to obtain locally conductive regions in an insulating material, for example for O-electronics applications. Figure 18. illustrates the variations of surface conductivity of the photoresistant polymer HPR-204 as function of the impinging dose of 2 MeV Ar^+ ions. The conductivity increases by four to five orders of magnitude and reaches the values of ion bombarded amorphous carbon or disordered metals [37].

Figure 18. Resistivity changes of 2 MeV Ar^+ ion bombarded polymers (HPR-204) as function of ion dose in comparison with amorphous carbon

Another possibility for obtaining local conductivity is the irradiation of intrinsically conductive polymers such as polypyrrole or polythiophene. In this case the irradiation destroys the conductive properties, and, if done through a mask, leaves only the shaded areas conductive. Figure 19. shows an example of such a structure with subsequent copper deposition on the conductive areas [38], [39].

Figure 19. Galvanic deposition of copper on the shaded areas of a conducting polymer bombarded with argon ions through a mask (size of the structures 13.5 µm)

Production of Microfilters. Microfilters can be produced by high energy ion beams (typically 100 MeV). The stopping track of the ions in polymers can be etched by alkaline solutions into very small channels suitable for special filtering or separation problems [40].

Glass. In the case of glass ion beam techniques have mainly been used to change its *optical properties*. These alterations range from the implantation of color centers (rare earth ions, for example) with the aim of flat screen production to the generation of wave guides for light. In the latter field a number of groups are working. The basic principle is the local implantation of metals which are not soluble in the glass and thus form small precipitates, causing local changes in the reflectivity of the materials [41], [42].

In addition ion beams are also used for polishing or machining high precision optical lenses in the nanometer-regime by sputtering.

Ceramics. Here the improvement of the mechanical surface properties like hardness, friction, and cracking behavior were the main subjects of application oriented studies. Especially nitrogen implantation in hard metals and in silicon nitride showed a considerable potential for crack reduction and the formation of intermediate solid lubrication layers [43], [44].

4.3.2. *Metallization and Ion Beam Assisted Coatings*

Ion beam mixing and ion beam assisted deposition are excellent methods for metallizing polymers, ceramics, and glass. In addition also compound layers or multilayers can be deposited on these substrates.

The advantage of ion beam techniques in comparison with pure evaporation is the greatly improved adhesion, and the low processing temperature, in comparison with PVD methods. The latter is especially important for the polymer case.

Metallizing of Polymers. Metallized polymers find broad applications in microelectronics as base materials for circuit boards, for electronic shielding in several industrial branches and for decorative and package purpose. Well established techniques are galvanic deposition and vacuum evaporation with or without prior plasma cleaning and roughening. Because of the low processing temperature and because they are not entailed with surface roughening, ion beam techniques can be used in cases were very smooth surfaces are needed, or for polymers which are difficult to metallize, such as high temperature thermoplastics [45], [46].

The factors affecting adhesion of metal layers on substrates are compiled in Figure 20. Most of these factors can be modified by ion bombardment, especially the film stress and the chemistry and morphology of the interface. This is illustrated in Figure 21. were the adhesion of thin copper layers on polyethersulfone (PES), measured by the peel test, is plotted as a function of the mixing ion species and the ion energy [47]. Before peeling the original Cu-layers have to be thickened to 20 µm by galvanic means.

Figure 20. Schematic representation of the factors affecting the adhesion of metal films on polymer or ceramic substrates

Figure 21. Adhesion of copper deposited on polyethersulfone (PES) after bombardment with different ion species measured by the peel test (ion dose $10^{14}/cm^2$; ion energy 60 keV or 120 keV; PVD: deposition without bombardment)

A layer deposited by vacuum evaporation shows initially no adhesion, upon bombardment the adhesion first increases with increasing electronic energy loss of the ion beam and goes through a maximum. The decrease after the maximum is caused by the increasing importance of nuclear energy loss in the higher mass region, leading to a destruction of the polymer skeleton. Similar effects have also been observed using ions with higher energy in the range of a few 100 keV–10 GeV [48]. The IBAD technique can also be used for improving the metal adhesion on polymers. The obtainable effects are very much dependent on the chemical composition of the polymer. In the case of polyethersulfone only very small ion doses (expressed in terms of the ion to atom arrival ratio I/A) of argon ions in the energy range of 2.5 – 5 keV or higher doses of low energy ions of 0.5 – 1 keV lead to considerable improvements. In Figure 22. the adhesion force, measured by the pull off test, is plotted as function of I/A for several energies. Interestingly, especially polyphenylenesulfide (PPS) is rather difficult to metallize with the established techniques. In some cases also a Ti intermediate layer improves the situation.

Figure 22. Adhesion force of a copper layer deposited on polyphenylensulfide (PPS) by ion beam assisted deposition as function of the ion/atom arrival ratio, measured by the pull off test (parameter is the argon ion energy)

(♦) 0.5 keV; (|) 1 keV (■); 2.5 keV; (●) 5 keV; (▲) 7.5 keV; (▼) 10 keV

Metallization by IBAD has been used also for medical purposes. Polymer tubes which are applied for “in body” therapy of kidney diseases have been coated with thin silver layers of excellent adhesion. Silver has bactericidal properties and thus helps to avoid unwanted inflammations.

Metallization of Ceramics. Only little work has been done on metallization of ceramics by ion beam mixing or IBAD. One example for applications is again the formation of conductive layers on an insulating substrate, another one are adhesive coatings with low friction coefficient. Si_3N_4 and Y stabilized ZrO_2 (PSZ) were coated with a number of metals and subsequently irradiated with 140 keV Ar^+ ions.

Under the running conditions of a Diesel engine the friction coefficient was reduced by nearly one order of magnitude for the case of a Ni–Ti double layer [49].

[Top of Page]

5. Outlook

At present the cost of non mass analyzed ion implantation (nitrogen for example) is ≈ 0.20 € for an implanted dose of 10^{15} ions/cm^2 and ≈ 0.70 – 1 € for 10^{17} ions/cm^2. Metal ion implantations with the MEVVA source was estimated in the USA to range around 0.10 €/cm^2.

These figures show that modifications requiring low ion doses, like in the case of polymers, are relatively cheap to perform. Also the PIII technique is somewhat less expensive than ion beam implantation. Ion beam assisted deposition is already used routinely in the optical industry and for small series or development work in many other industrial fields. The costs of the modification depend on one hand on the investment, which is usually 10–30 % higher than that for a conventional PVD plant. Secondly the beam power of the ion source and the thickness of the coating determine the cost per square centimeter. A 3–5 µm thick TiN layer may be realized at present for 1–2 €/cm^2. With an optimized dedicated machine 0.25 €/cm^2 should be no problem.

At present plants with continuous coil coating or large area capability using powerful slit extraction sources are under development [50]. With such plants cost reductions may be realized, especially for cases where the ion beam is only used for precleaning by sputtering or for the production of thin interface or barrier coatings. The thickening of the coating is then performed by pure evaporation.

The future trends for applications of ion beam techniques are on the one hand dependent on the further development of high power broad beam sources and continuous working plants, on the other hand on the future requirements for high-tech coatings. Fields of high potential for special surfaces and coatings are:

- Implants and materials for medical and biological use like internal prostheses, screws, fixations, infusion tubes, catheters etc.
- UV- and X-ray optics, specially surface finishing of lenses by sputtering with nanometer precision.
- Texturing and metallizing of polymers and ceramics for circuit boards and sensors.
- Coatings and nitriding of highly temperature sensitive materials like Al, Mg, and their alloys.
- Surface modification and machining of micromechanical devices and creation of nanostructures by using mask techniques or highly focused ion beams.

1. Introduction

Inulin is a storage carbohydrate found in many plants. It has formed part of the daily diet of humans for some centuries as it naturally occurs in many vegetables, fruit, and cereals. Inulin is industrially obtained from chicory roots and used as a food ingredient offering both interesting nutritional properties and important technological benefits. It significantly improves the organoleptic characteristics of food and drinks, increases the stability of foams and emulsions, and shows a fat-like behavior when used as a gel in water.

Inulin was first isolated from *Inula helenium* by ROSE, a German scientist, in 1804 [1] but it was THOMSON who called this substance inulin [2]. One pioneer in fructan research was the German plant physiologist JULIUS SACHS [3] who detected inulin in the tubers of *Dahlia*, Jerusalem artichoke (*Helianthus tuberosus*), and *Inula helenium* after ethanol

precipitation. Already in the beginning of the 20th century, feeding diabetic patients with inulin was reported to be beneficial [4]. Especially since the 1990s, a spectacular increase in the number of publications dealing with the technological and nutritional benefits of inulin has been observed [5].

[Top of Page]

2. Chemical Structure

Inulin [9005-80-5] is a polydisperse carbohydrate material consisting mainly, if not exclusively, of fructose [57-48-7] units, linked by β(2 ⟶1) bonds [6]. A starting glucose [50-99-7] moiety can be present in the chain but is not necessary. *Levan*, formed by certain bacteria, consists mainly or exclusively of β(2 ⟶6) linked fructosyl-fructose units. As for inulin, glucose can be present, but again is not necessary. *Fructan* is a more general name, used for any compound in which fructosyl-fructose bonds constitute the majority of linkages. The term fructan therefore covers both inulin and levan.

Referring to the definition of inulin, both GF_n and F_n compounds (F being a fructosyl unit and G a glucosyl unit) are included under that same nomenclature. In chicory inulin, *n*, the number of fructose units, can vary from 2 to 60 [7], i.e., inulin is a mixture of oligomers and polymers. Its molecular structure is shown in Figure 1.

Figure 1. Chemical structure of inulin

The degree of polymerization (DP) and the possible presence of branches are important properties because they influence the functionality of inulin. Therefore a strict distinction must be made between inulin from plant origin and inulin from bacterial origin. The DP of plant inulin is rather low (DP < 200) and varies according to the plant species, weather conditions and the physiological age of the plant. Standard chicory inulin has an average DP of about 10–12. Long-chain chicory inulin, from which the lower DP fraction has been physically removed and which has an average DP of about 25, is also available. In contrast, bacterial inulin has a very high DP, ranging from 10000 to over 100000 (10^6 to 10^7 dalton). It is branched (≥15 %) which results in a completely different behavior in aqueous systems.

[Top of Page]

3. Physical and Chemical Properties

Chicory inulin is available as a white, odorless powder with a high purity and a defined chemical composition. The taste is neutral, without any off-flavor or aftertaste. Standard chicory inulin is slightly sweet (10 % sweetness in comparison with sucrose), whereas long-chain inulin is not sweet at all [5] (see also Physiological Properties). The physicochemical properties of chicory inulin are summarized in Table 1.

Table 1. Physicochemical properties of chicory inulin

	Standard inulin	Long-chain inulin
Chemical structure	GF_n ($2 \le n \le 60$)	GF_n ($10 \le n \le 60$)
Average degree of polymerization	12	25
Dry matter (%)	> 95	> 95
Inulin content (% of d.m.)	92	99.5
Sugar content (% of d.m.)	8	0.5
pH (10 wt %)	5-7	5-7
Sulfated ash (% of d.m.)	< 0.2	< 0.2
Heavy metals (ppm of d.m.)	< 0.2	< 0.2
Appearance	white powder	white powder
Taste	neutral	neutral
Sweetness (vs sucrose = 100 %)	10 %	none
Solubility in water at 25 °C (g/L)	120	10
Viscosity in water (5 %) at 10 °C (mPa·s)	1.6	2.4
Heat stability	good	good
Acid stability	fair	good
Functionality in foods	fat replacement	

	body and mouthfeel
	texture improvement
	foam stabilization
	emulsion stabilization
	synergy with gelling agents

*G = glucosyl unit. F = fructosyl unit. d.m. = dry matter.

Physical Properties. Chicory inulin is moderately soluble in water (about 10 % at room temperature) which allows its incorporation in watery systems without precipitation. The viscosity of chicory inulin solutions is rather low, e.g., 1.65 mPa·s at 10 °C for a 5 % dry matter (d.m.) solution and 100 mPa·s for a 30 % d.m. solution [5]. Dissolved inulin exerts a small effect on the freezing and boiling point of water (e.g., 15 % chicory inulin decreases the freezing point by 0.5 °C).

At high concentration (>25 % in water for standard chicory inulin and >15 % for long-chain inulin), inulin has gelling properties and forms a particle gel network after shearing.

The gel strength obtained depends on the inulin concentration and total dry substance content, on the shearing parameters (such as temperature, time, speed, or pressure) and also on the type of shearing device used, but is not influenced by pH (between pH 4 and 9). Electron cryomicroscopy has shown that such an inulin gel is composed of a three-dimensional network of insoluble submicron inulin particles in water. These particles of about 100 nm in size aggregate to form larger clusters having a diameter of 1 to 5 µm. Large amounts of water are immobilized in that network, as determined by NMR experiments. X-ray diffraction confirmed the crystalline nature of the gel particles whereas the starting inulin powder is essentially amorphous.

An inulin gel exhibits a viscoelastic rheological behavior and shows shear-thinning and thixotropic properties. The gel is characterized by a relatively low yield stress (e.g., 1540 Pa for a gel of 30 % standard inulin in water at 25 °C). Inulin also displays synergistic effects with most gelling agents (e.g., gelatin, alginate, κ- and ι-carrageenan, gellan gum, maltodextrin) [10].

Furthermore, inulin improves the stability of foams and emulsions, e.g., in aerated dairy desserts, ice creams, table spreads, and sauces. It can therefore replace other stabilizers in different food products.

Chemical Properties. Under strongly acidic conditions, the β(2 ⟶1) bonds between the fructose units can be (partially) hydrolyzed and fructose is formed. Inulin is stable in applications with a pH > 4. Even at lower pH values, the hydrolysis of inulin is limited to less than 10 % if the products either have a high dry substance content (>70 %), are stored at a low temperature (<10 °C), or have a short shelf-life.

[Top of Page]

4. Physiological Properties

Inulin behaves like a bulk ingredient, contributing to body and mouthfeel. It is often used in combination with intense sweeteners to provide a rounder mouthfeel and a better-sustained flavor with reduced aftertaste.

Inulin provides several interesting nutritional benefits to animals and humans (see Table 2) [11]. Thanks to its β (2 ⟶1) bonds, which the digestive enzymes of humans cannot hydrolyze, inulin passes through the mouth, the stomach, and the small intestine without undergoing any significant change and without being absorbed [12]. Inulin thus enters the colon almost quantitatively and there it is completely metabolized by the intestinal bacteria [13], mainly to short-chain fatty acids (SCFA), bacterial biomass and gases. Only the SCFA contribute to the host's energy metabolism, which explains the reduced caloric value of inulin (between 1 and 1.5 kcal/g). Inulin has no influence on blood glucose and insulin levels when ingested orally and it has been known as a food for diabetics since the beginning of the 20th century [4], [14].

Table 2. Physiological properties of inulin

Strong evidence:
Nondigestibility and low caloric value (1–1.5 kcal/g)
Suitable for diabetics
Soluble dietary fiber
Stool bulking effect: increase in stool weight and stool frequency, relief of constipation
Modulation of the gut flora composition, stimulating beneficial bacteria (*Bifidobacteria*) and repressing harmful ones (*Clostridia*): prebiotic / bifidogenic effect
Improvement of calcium (and magnesium) bioavailability
Promising evidence:
Reduction of serum and liver triglycerides and serum insulin levels
Reduction of colon cancer risk (in animal models)

Modulation of immune response and resistance

Protection against intestinal disorders and infections

Improved well-being

Inulin is a soluble dietary fiber [15] which induces typical effects on the gut function, such as a reduction of the intestinal pH, a relief of constipation, and an increase in stool weight and frequency (or bulking effect). Its fecal bulking effect is similar to that of other soluble fibers such as pectin and guar gum [16]: each gram ingested increases the fecal wet weight by about 2 g. Inulin also has modulating effects on the lipid metabolism, e.g., by reducing serum and liver triglycerides [19], [20].

In the colon, inulin selectively promotes the growth and metabolic activity of beneficial bacteria, mainly *Bifidobacteria*, while repressing harmful ones, e.g., *Clostridia* (prebiotic or bifidogenic effect, ⟶ Health Value Added Foods – Prebiotics) [17], [21], [22]. A daily intake of 5 to 10 g of inulin is sufficient to significantly enhance *Bifidobacteria* in humans [23].

Recent research indicates that inulin also has a significant chemopreventive potential [24]. Indeed, it can prevent the formation of precancerous lesions and tumors in the colon of rats. Long-chain inulin is more effective than shorter-chain fructans. Synergistic effects were observed when inulin and *Bifidobacteria* were administered together as a synbiotic [25]. It was furthermore demonstrated that inulin inhibits the development of cancer cells transplanted in the thigh or in the peritoneum of mice [26].

Inulin also increases the intestinal absorption of calcium, iron, and magnesium as well as the bone mineral density in rats [27], [28]. Studies in human volunteers also show an increased calcium absorption upon administration of inulin [29], [30], [31].

[Top of Page]

5. Resources and Raw Materials

After starch, fructans are the most abundant nonstructural polysaccharides found in nature. They are present in a wide variety of plants and in some bacteria. Most literature on the natural occurrence of fructans does not differentiate, however, between levan and inulin.

Fructan-producing plants are commonly present among the grasses (1200 species), whereas 15 % of the flowering plants produce fructans in significant amounts. Fructan-producing plants are widely spread within the *Liliaceae* (3500 species) and most frequently among the *Compositae* (25 000 species) [32]. A plant with a special status is the *Agave Azul Tequila Weber (Liliaceae)*: Tequila is an alcoholic drink made by fermentation from highly branched fructan present in this plant.

Inulin-containing plants that are commonly used in the human diet belong mainly to either the *Liliaceae* (leek, onion, garlic, and asparagus) or the *Compositae* (Jerusalem artichoke, chicory, and yacon) as shown in Table 3 [33].

Table 3. Inulin content (% of fresh weight) of plants that are commonly used in human nutrition

Source	Edible parts	Dry solids content	Inulin content
Artichoke	leave-heart	14–16	3–10
Banana	fruit	24–26	0.3–0.7
Barley	cereal	NA	0.5–1.5*
Burdock	root	21–25	3.5–4.0
Camas	bulb	31–50	12–22
Chicory	root	20–25	15–20
Dandelion	leaves	50–55*	12–15
Garlic	bulb	40–45*	9–16
Jerusalem artichoke	tuber	19–25	14–19
Leek	bulb	15–20*	3–10
Murnong	root	25–28	8–13
Onion	bulb	6–12	2–6
Rye	cereal	88–90	0.5–1*
Salsify	root	20–22	4–11
Yacon	root	13–31	3–19

NA: figures not available.
*Estimated.

Bacterial inulin is produced by *Streptococcus mutans*, the spores of *Aspergillus sydowi* and *Lactobacillus reuteri*. A high

degree of branching (≥15 %) is observed in these fructans.

Given their high inulin content (>10 %), dahlia, Jerusalem artichoke, and chicory (*Cichorium intybus*) have been considered as candidates for industrial production of inulin [34].

5.1. Dahlia

Many dahlia cultivars are available, but they have all been selected for their flowers, rather than for inulin production. The tuberous roots can be propagated only if attached to a piece of stem tissue. When propagated from seed, sowing has to be delayed until late spring, given dahlia's extreme sensitivity to frost. Mechanical harvesting of the tubers is feasible only on sandy grounds. Although the DP of dahlia inulin is higher than that of chicory inulin, inulin yield from dahlia is only half that of chicory (see Table 4). For all these reasons, dahlia does not appear as an interesting crop for inulin production.

Table 4. Yields and composition of Dahlia, Jerusalem artichoke and Chicory

		Dahlia	Jerusalem artichoke	Chicory
Roots or tubers (t/ha)				
	average	25	42	43.5
	variation		35–60	25–75
d.m. (%)				
	average	18	22	22.5
	variation	15–22	19–25	20–25
Inulin (%)				
	average	11	16	16.5
	variation	10–12	14–18	15–18
Inulin (t/ha)		2.5–3	4.5–8.5	5–11
Mean DP		13–20	6–10	10–14

d.m. = dry matter. DP = degree of polymerization.

5.2. Jerusalem Artichoke

Jerusalem artichoke shows a rather high inulin content (14–19 %). It is not recommended to cultivate Jerusalem artichoke in clay-soil as the tubers are small and irregular, hence bringing a lot of soil attached to them. Although Jerusalem artichoke is frost tolerant, its inulin metabolism is very sensitive to cold. As Jerusalem artichoke inulin has only 20 % of chains with a degree of polymerization longer than 10, it is unsuited for several food and non-food applications (see Table 4).

5.3. Chicory

Chicory is a biennial plant. During the first season, the plants remain in the vegetative phase and make only leaves, tap roots, and fibrous roots. The roots look like small oblong sugar beets. The inulin content is high (16–18 %) and fairly constant from year to year for a given region. Yields in tons of roots per hectare (around 45 t/ha) show a wider variation (Table 4). In order to keep the chicory culture healthy a strict crop rotation is imposed (once every five years). Industrially, inulin is produced from chicory. The chicory used for inulin production (*Cichorium intybus*) is of the same type as the one used for the production of a coffee substitute (after roasting).

[Top of Page]

6. Production

The production of chicory inulin consists of two steps. The first step includes the extraction and primary purification, resulting in a raw impure syrup. The second step is the refining phase, which results in a purified commercial end product [5], [35].

6.1. First Step

The first process phase is virtually similar to sugar beet processing. Roots are harvested and stored in piles on the field. To minimize losses, no more than 7 days should elapse between harvest and delivery to the factory. The roots are then transported to the factory by truck, weighed, and carefully stored on the court. From there, they are transported with a stream of water inside the factory, where they are washed and sliced. Raw inulin is extracted from the resulting “chips” with hot water in a countercurrent diffuser. The leached “chips” are dried and sold as animal feed. A first purification step is applied to the extraction juice by liming and carbonation at high pH. The resulting $CaCO_3$ sludge precipitates easily.

Peptides, some anions, degraded proteins, and colloids are trapped in its flocs. This generates a foam-type product, which is used by the farmers to improve the soil structure, as it is rich in calcium and organic matter.

6.2. Second Step

The raw juice is further refined using cationic and anionic ion exchange resins for demineralization and active carbon for decolorization. This technology is comparable to the one used in starch processing. After demineralization and

decolorization, the juice is passed over a 0.2 µm filter for sterilization, before being evaporated and spray-dried. The resulting standard inulin (RAFTILINE ST, ORAFTI) has an average chain length which reflects the original DP distribution present in the chicory root (between 10 and 12). A special long-chain grade inulin (RAFTILINE HP, ORAFTI), with an average DP >23 is also available. It is made by physical elimination of the small DP fraction [36].

6.3. Environmental Aspects

The chemicals used for regeneration of the ion exchangers are not NaOH and HCl as usual, but NH_3 and H_2SO_4. The advantage is that the effluents can be converted into reusable byproducts. At high concentrations, easily crystallizing salts such as $(NH_4)_2SO_4$ and K_2SO_4 precipitate, are separated from the mother liquor and sold commercially as fertilizers. The mother liquor is further evaporated into a stable product that is sold as animal feed because of its high organic matter content. This way the circle between the processing industry and the agriculture is fully closed.

[Top of Page]

7. Uses

7.1. Food Applications

In food and drink products, inulin can be used for either its nutritional advantages or its technological properties, but it is often applied to offer a double benefit: an improved organoleptic quality and a better-balanced nutritional composition. Table 5 gives an overview of the applications of inulin in foods and drinks.

The use of inulin as a dietary fiber ingredient is easy and often leads to an improved taste and texture [37]. Its solubility allows fiber incorporation in watery systems such as drinks, dairy products, and table spreads. Inulin is more and more used in “functional foods”, especially in a whole range of dairy products, as a prebiotic ingredient (⟶ Health Value Added Foods – Prebiotics).

Table 5. Applications of inulin in foods and drinks

Application	Functionality	Dosage level (wt %)
Dairy products (yogurts, cheeses, desserts, drinks)	fat replacement body and mouthfeel foam stabilization fiber and prebiotic	2–10
Frozen desserts	fat replacement texture improvement melting behavior low caloric value	2–10
Table spreads and butter-like products	fat replacement texture and spreadability emulsion stabilization replacement of gelatine fiber and prebiotic	2–10
Baked goods and breads	fiber and prebiotic moisture retention	2–15
Breakfast cereals and extruded snacks	fiber and prebiotic crispness and expansion low caloric value	2–20
Fillings	fat replacement texture improvement	2–30
Salad-dressings and sauces	fat replacement mouthfeel and body emulsion stabilization	2–10
Meat products	fat replacement texture and stability fiber	2–10
Dietetic products and meal replacers	fat replacement synergy with intense sweeteners body and mouthfeel fiber and low calorie	2–15
Chocolate	sugar replacement and	5–30

	fiber and heat resistance	
Tablets	sugar replacement fiber and prebiotic	5–75

Thanks to its specific gelling characteristics, inulin allows the development of low-fat foods without compromising on taste and texture. When the fructan is thoroughly mixed with water or another aqueous liquid, using a shearing device such as a rotor-stator mixer or a homogenizer, a white creamy structure results which can easily be incorporated in foods to replace fat up to 100 % [5], a process patented by RAFFINERIE TIRLEMONTOISE/ORAFTI [9]. In table spreads, both fat and water-continuous, inulin allows the replacement of significant amounts of fat and the stabilization of the emulsion, while providing a short spreadable texture. In low-fat dairy products, such as fresh cheese, cream cheese or processed cheese, the addition of a few percents of inulin gives a creamier mouthfeel and imparts a better-balanced round flavor. Inulin also is destined to be used as a fat replacer in frozen desserts, providing an easy processing, a fatty mouthfeel, excellent melting properties, as well as freeze-thaw stability, without any unwanted off-flavor. Fat-reduced meat products, such as sausages and pâtés with a creamier and juicier mouthfeel and an improved stability due to better water immobilization, can be obtained using inulin as ingredient. The synergistic effect of inulin with other gelling agents constitutes an additional advantage in all these applications.

Special “instant” qualities, which do not require shearing to give stable homogeneous gels also have been developed (using specific spray-drying technology) and patented.

The incorporation of inulin (1 to 3 %) in diet fruit yogurts, possibly through the fruit preparation, improves the mouthfeel, and offers a synergistic taste effect in combination with aspartame and/or acesulfame K [8]. Inulin furthermore increases the stability of foams and mousses: its incorporation at 1 to 5 % into dairy-based aerated desserts improves the processibility and upgrades the quality.

Inulin also has found an interesting application as a low calorie bulk ingredient in chocolate without added sugar, often in combination with a polyol. It is also used as a dietary fiber or sugar replacer in tablets.

7.2. Inulin Derivatives for Non-Food Applications

In the context of product development based on renewable resources, different types of chemical modifications have been performed using inulin as raw material [38]. From the industrial point of view, three reaction types are most interesting: oxidation, carboxymethylation, and hydrophobization.

7.2.1. *Oxidation*

Although inulin can be oxidized in several ways, a one-step reaction using sodium hypochlorite as the oxidant together with sodium bromide as a catalyst is generally used (see Fig. 2) [38-41].

Figure 2. Oxidation of inulin

Under well-controlled conditions (slow addition of the oxidant in 4 to 6 h, constant pH of 9.5, addition of a concentrated NaOH solution) oxidation occurs almost exclusively at the C3-C4 fructose bond, resulting in a ring-opened inulin known as dicarboxyinulin (DCI). Due to this fructose ring-opening and the direct formation of the calcium-complexing oxydiacetate (ODA) structure, DCI shows excellent calcium sequestering properties (SC) (2.0–2.5 mmol Ca/g active substance) [39]. Moreover, due to the linear relationship between the degree of oxidation, the formation of the ODA structure and hence the SC value, it is easy to compromise between the oxidation degree and the biodegradability.

7.2.2. *Carboxymethylation*

Heating an aqueous solution of inulin in the presence of an excess of sodium hydroxide with monochloroacetic acid results in the production of O-(carboxymethyl) inulin (CMI) (see Fig. 3) [42, 43]. The reaction efficiency of this etherification very much depends on parameters such as reaction temperature and water content: lower water content and temperature result in a higher efficiency.

Figure 3. Carboxymethylation of inulin

CMI is a good inhibitor of the crystallization of calcium carbonate. Even at very low concentrations (5–200 ppm), CMI can extend the induction period for crystallization by absorption of the carboxylate groups onto the crystal surfaces.

7.2.3. *Hydrophobization*

Hydrophobization of inulin, e.g., grafting of alkyl chains on the inulin backbone, can be done in two different ways: by esterification or by carbamoylation.

The esterification of inulin is carried out by reaction with acid chlorides or anhydrides; the introduced alkyl chain can range from 1 to 22 carbon atoms (see Fig. 4) [44]. The reaction is usually performed either in solvents such as pyridine, *N,N*-dimethylformamide or dimethyl sulfoxide, or solvent-free, using a kneader or (preferably) an extruder. As catalyst 4-(dimethylamino)pyridine, sodium acetate, or potassium carbonate can be used.

Figure 4. Esterification of inulin

The carbamoylation of inulin (modification of inulin with an alkyl-isocyanate) is done in a polar organic solvent such as *N,N*-dimethylformamide or *N*-methylpyrolidinone, as shown in Figure 5 [45].

Figure 5. Carbamoylation of inulin

Both the esterified and carbamoylated inulins show interesting interfacial properties. Depending on the length of the alkyl chain and the degree of substitution these inulin derivatives are able to decrease the surface tension of aqueous solutions and the interfacial tension at an oil–water interface [46]. Moreover, the critical micelle concentration (cmc) of hydrophobized inulins is approximately 0.01 % (w/v). The above described tensioactive properties make these molecules suitable for use in detergent applications, cosmetics, or crop protection formulations.

[Top of Page]

8. Analysis

Although several analytical techniques are available for the determination of inulin, no single method gives a complete and quantitative analysis of all the components present. A combination of different methods is therefore often necessary.

8.1. HPLC

Two columns in series in the K^+ form are used (Aminex HPX-87 K^+) for optimal separation. The separation into fructose, glucose, DFA (difructose-dianhydride), GF, F_2, and F_3 is optimal, but further separation into DP3, DP4, and DP ≥ 5 is not very precise. DP3 and DP4 fractions are not pure, but include GF_2 plus F_4 and GF_3 plus F_5, respectively. The fraction of DP ≥ 5 is the integrated sum of DP5 and higher DP molecules. As this fraction might include small oligosaccharides as well as high DP inulins, a fixed response factor can not be determined, which makes this analysis unsuited for quantitative inulin determination. The method is well adapted to evaluate the relative amounts of the different compounds present; especially the amounts of the non-inulin compounds glucose, fructose, and sucrose.

8.2. Gas Chromatography

A high temperature capillary gas chromatographic method has been developed for the quantitative determination of inulin-type oligosaccharides with DP <10 [47]. Sample preparation involves oximetrimethylsilylation (oxymation) and silylation of the extracted sugars. The method is accurate and specific.

Moreover $\beta(2 \longrightarrow 6)$ oligosaccharides can be clearly distinguished from $\beta(2 \longrightarrow 1)$ compounds and GF_n molecules from F_n molecules.

8.3. HPAEC Analysis (Dionex)

A differentiation between GF_n and F_n compounds can be made using High Pressure Anion Exchange Chromatography (HPAEC) which furthermore provides a fingerprint of the molecular mass distribution of inulin. This analytical technique uses a Dionex series 4000 ion chromatograph (Carbo-Pac PA-1 column) coupled with a Pulsed Amperometric Detector (PAD). During the analysis, the carbohydrates are eluted with a NaOH/NaAc gradient [48]. The major drawback of HPAEC-PAD is that it is very difficult to quantify the high DP compounds, due to the lack of appropriate standards and the reduced sensitivity of the PAD detector for high DP polymers.

When coupling HPAEC with a Pulsed Electrochemical Detector (PED), oligomers up to DP17 can be quantified and the weight fraction of each compound present can be calculated [49].

The average degree of polymerization is determined by the fructose to glucose ratio after complete hydrolysis with inulinase (Fructozyme, NOVO) (at pH 4.5 and 60 °C for 30 min): $\mathrm{D\bar{P}n} = \mathrm{F/G} + 1$.

8.4. Permethylation

The type of linkage and the occurrence of branching are checked by permethylation followed by reductive cleavage and in situ acetylation [50]. The reaction products are analyzed using capillary gas chromatography (CGC).

8.5. Quantitative Determination

The official AOAC method no. 997.08 was developed to quantitatively measure inulin, e.g., in food [51]. An overview of the method is given in Figure 6.

Figure 6. Flow diagram of the enzymatic fructan determination method (AOAC no. 997.08)

If inulin is the only compound present in the sample, the method consists only of steps 1 and 3. The inulin is extracted from a substrate at 85 °C for 10 min; part of the extract is put apart for determination of free fructose, glucose, and sucrose by any reliable chromatographic method available (HPLC, HGC, or HPAEC-PAD), the other part is submitted to an enzymatic hydrolysis, identical to the one described above for DP determination. After this hydrolysis step, resulting fructose, and glucose are determined again by chromatography. By subtracting the initial glucose, fructose, and sucrose contents from the final ones, the following formula can be applied:

$$\text{Inulin} = k(\text{G}_{\text{inu}} + \text{F}_{\text{inu}})$$

where k (<1) depends on the DP of the inulin analyzed and corrects for the water gain after hydrolysis. G_{inu} and F_{inu} are glucose and fructose, respectively, strictly originating from inulin.

If a complex sample needs to be analyzed, as is often the case when dealing with food products, an amyloglucosidase treatment must be included before the last step and an extra sugar analysis performed to avoid overestimation of the glucose originating from starch and maltodextrins present.

Although AOAC method 997.08 is very reliable, it is very labor intensive and requires the use of chromatographic apparatus. AOAC method no. 999.03, based on the use of enzymes for hydrolysis and sugars determinations, just requires a spectrophotometer and some other standard lab equipment [52]. This method is reliable for the determination of inulin, but it cannot be used for the determination of oligosaccharides obtained by hydrolysis of inulin, as F_n-type compounds are significantly underestimated.

[Top of Page]

9. Legal Aspects

Inulin is legally classified as food or food ingredient, and not as additive, in all countries where it is used. As a consequence, inulin is not listed as “accepted food additive” in the standard positive lists, e.g., from the European Union or from Codex Alimentarius. In the USA, inulin was declared “Generally Recognized As Safe” in 1992.

Inulin is classified as ‘dietary fiber’ in all European countries and in most other countries. It also complies with the Codex Alimentarius definition of Dietary Fiber (Codex Guidelines on Nutrition Labelling CAC/GL 2-1985, Rev. 1 - 1993).

[Top of Page]

10. Economic Aspects and Trade Names

Currently, inulin is produced industrially by three companies, all of them using chicory as raw material: ORAFTI, Belgium, a subsidiary of RAFFINERIE TIRLEMONTOISE (trade names RAFTILINE for food applications, RAFTIFEED for animal feed and INUTEC for non-food uses), WARCOING, Belgium (trade name FIBRULINE) and SENSUS, The Netherlands, a subsidiary of COSUN (trade name FRUTAFIT).

Chicory processing has evolved from a laboratory and pilot plant project to a full industrial scale. While the production of inulin as such is not regulated by quota, the production of chicory fructose (obtained by hydrolysis of inulin, see ⟶ Fructose) is. As these quota are officially attributed by the European Union, they give an idea of the production scale [5].

The fact that the land surface assigned to chicory for inulin/fructose production has evolved from a few hundred hectares in 1990 to more than 20 000 ha in 2000 is another indication for the growth of the inulin-related business.

[Top of Page]

1. Introduction

1.1. Goals of Industrial Freeze-Drying

The freeze drying of pharmaceutical and biological products is performed for one or more of the following reasons:

1. The ingredients of the formulation are not stable in the liquid state, and other methods of water removal destroy or reduce the active ingredient
2. The amount of active ingredients is very small, and the dosing of liquids can be better controlled than that of a powder
3. Sterilization of the vials before filling and filling into the final container minimizes handling and reduces possible contamination
4. The desired structure of the product can only be achieved by solidifying it and removing the solvent in this phase

The freeze drying of food aims at convenient, natural, storage-stable products. The weight reduction to mostly 10 or 20 % is of interest only in some cases. The main freeze-dried food products are coffee extract, spices, some fruits, and meat. Marketing and economy are the deciding criteria for freeze-dried food.

Freeze-drying of collagen is carried out on an industrial scale; oxides and ceramics are more or less in a development phase.

1.2. Steps of the freeze-drying process

The first step is to transform the solvent, which in all cases in this article is water, into a form with drastically reduced mobility of its molecules. This can be in the form of ice crystals, an amorphous phase, or as residual water in a highly viscous concentrate produced by freeze-concentration. Ice crystals are often undesired, e.g., in organic cells and their suspensions, in most protein solutions, and in several food products. The solidification of the product into a structure, its “freezing”, is a decisive step in freeze-drying. The structure of the frozen product decides:

- Whether a product can be dried at all
- The maximum temperature at which the frozen water can be sublimed
- The pressure at which the remaining water must be desorbed
- The minimum water content that can be achieved at the end of drying
- At which temperature and how long the product can be safely stored

These five points of course also depend on the ingredients of the product. Ingredients and freezing method decide the drying process and the storage capability.

The second step is the sublimation of the ice, known as main drying (MD). Theoretically, this is possible at atmospheric pressure, but three facts make such a process technically impossible, in spite of many trials and ideas:

1. 1 kg of ice sublimed at 0.6 mbar has a volume of ca. 2000 m^3. The air volume to transport this water vapor must be in the ratio of 0.6 to 1000 mbar, i.e., ca. 3.3×10^6 m^3 per kilogram of ice.
2. If only the diffusion of water vapor in quiescent air is used and the distance between ice and condenser is 100 cm, only 4×10^{-2} g m^{-2} h^{-1} can be transported.
3. If the product to be dried is mixed with a strong water vapor absorber, the distance between ice and absorber is very small, but firstly an acceptable absorber must be found, and secondly product and absorber must be separated quantitatively after drying.

Therefore, only vacuum processes are discussed in this article.

The third step is the desorption of water from the solid, called secondary drying (SD). Normally this process starts at a water content (called RM) of ca. 10 % (or 0.1 g water/g solids) and ends between 3 and 0.3 %, depending on the product.

Step four is the packing of the product in a packaging tight to water vapor and often to O_2. Vials with product are placed with a stopper in a semi-open position on the shelves of the freeze-dryer, and at the end of drying the stoppers are pushed into the closed position, either under vacuum or after venting the chamber with a defined gas of a prescribed pressure. Product in open trays, as most food, are vented in the chamber with a dry gas and packed in containers with as little uptake of water vapor or oxygen as possible from the air.

Step five is the storage of the product, which lasts 100 or normally 1000 times longer than the drying process. Long-term structural changes and/or chemical reactions will influence this part of the process. Generally the storage temperature and the water content at the beginning of storage will dominate over the product behavior.

1.3. Chemical Engineering Tasks in Industrial Freeze-Drying

Freeze-drying is a complex sequence of steps based on several scientific and technological disciplines: From biology to statistics, from pharmacy to thermodynamics, from mechanical engineering to production control and automation. In reviewing several thousand freeze-drying publications over the years, it becomes evident that the chemical engineering aspects are very often not recognized by pharmacists, biologists, and mechanical or production engineers. Often one can read excellent papers about structures of proteins, survival rates of cells or sugars as excipients, but the information on the freeze-drying process is limited to “frozen and freeze-dried”. It should therefore be a major task for the chemical engineers or for the process or production development group to inform all parties concerned about the unavoidable requirements of an industrial freeze-drying process. This can literally save millions in costs and months in time, as a few examples

illustrate:

1. In an automatically loaded and unloaded plant temperature sensors can not be used; freezing, main drying, and secondary drying processes must be controlled by other methods. If this is not realized during product and process development, a large part of the development might have to be repeated with other temperature measurement methods.
2. The selection of an optimum vial can easily influence the main drying time by a factor of two, some time up to a factor of four; the main drying time could be, e.g., 15 h, 30 h, or even 60 h for the same product, without changing anything but the vial. Changing the type of vial later will require a substantial amount work and time, or the cycles will be unnecessary long.
3. The uniformity of a large charge is a must in production. Influences of wall and door temperatures may not be recognized in laboratory or pilot plants. They are present but are not documented sufficiently to be transferred to a production plant. Substantial studies at the production plant may be required to achieve uniform production in the process time of the pilot plant. Details of such influences are described in Section Uniformity of Temperatures, Pressures, and Product.

Another task for chemical engineering is to study the possibility of partially or totally automating the total freeze-drying process. Sooner or later this will become a requirement for the following reasons: In the pharmaceutical industry freeze-drying plants are becoming larger and larger (50 000 to 100 000 vials per charge), and the value of the product per vial is increasing; one charge can represent often several million euros. Human errors, which inevitably occur, must be avoided as much as possible, and humans are the most frequent danger to sterility in the production area; their numbers should be reduced as much as possible. In freeze-drying of food the cost of operators is an important factor in the total cost; such plants are mostly run continuously seven days a week, and the number of operators should be minimized, as should their errors. The automation of production freeze-drying plants must be considered at all times. Automation adds to the process requirements as shown in example 1 above and influences several other steps, as shown in Section Process Automation.

[Top of Page]

2. Process Steps

2.1. Freezing

The result of cooling a solution or suspension below 0 °C depends on the type and the amount of nuclei available for crystallization, the degree of supercooling, the freezing rate (°C/min), the mobility of the water molecules in the product, and the end temperature of freezing. These influences are partially dependent on each other, but in simplified and general terms, the following cases can be distinguished:

- Slow freezing (rate < 0.5 °C/min): large ice crystals, mostly equilibrium conditions, freeze-concentration of solids most likely, water crystallizes to a maximum extent.
- Quick freezing (rate 0.5–2 °C/min): these rates can be achieved on the shelf of a freeze-drying plant, 2 °C/min only under special conditions.
- Fast freezing (5–300 °C/min): this can only be achieved with liquid nitrogen (LN_2) and above about 100 °C/min with droplet freezing in LN_2. Mostly small ice crystals are formed; supercooling can be substantially extended (e.g., 10–20 °C); freeze-concentration only in small regions distributed over the product; some water molecules have no time to move to a crystal or nucleus, and this water can behave mechanically like a solid, but during rewarming it will be in the liquid phase (unfrozen water).

In pure water without any nuclei for crystallization ice forms at ca. –40 °C. This process is called homogeneous crystallization, while crystallization in the presence of third particles is called heterogeneous crystallization.

In all cooling processes a situation in the product is reached in which the water molecules can no longer move to the nuclei or the ice crystals, since the mobility of the water molecules has become too small in the highly viscous surroundings. The amount of water still not crystallized at a typical temperature for the product is called unfreezable water (UFW). Figure 1 shows the phase diagram of water–glycerol: The three phases of ice which exist under normal pressure as a function of temperature are shown, and the time it takes to change from one type to another. If water vapor is condensed on a cold surface in a very thin film, amorphous ice is formed; it remains stable at –160 °C for a long time; as shown in Figure 1, the change from amorphous to cubic ice will take about 5×10^5 min, or more than a year. The rate of change depends very much on the temperature: at –135 °C the same change takes only 1 min. This change is called devitrification. At –125 °C the change from cubic to hexagonal ice takes about 1000 h, while at –65 °C only hexagonal ice is stable. This behavior of pure water changes if water solutions, suspensions in water, and mixtures with water are studied, as it is the case for virtually all products to be freeze-dried. Luyet [2] shows diagrammatically (Fig. 2) how various phase changes take place at different glycerol concentrations. At 60 % glycerol devitrification takes place at ca. –115 °C, and the devitrification temperature increases with increasing glycerol concentration to ca. –85 °C. However, such high concentrations of glycerol can not be used to freeze dry organic substances. The devitrification temperature T_g depends strongly on the content of unfrozen water; incompletely frozen products have a very low T_g (e.g., –85 °C), while this temperature can be much higher (e.g., –58 °C), if all water (apart from the UFW) is crystallized; this temperature is normally indicated as $T_{g'}$.

Figure 1. Phase diagram water–glycerin

On the left-hand side the dependence of the phase transformation time on the ice temperature is shown: At –140 °C

amorphous ice transforms into cubic ice in ca. 10 min. (Fig. 8 from [1]).

Figure 2. Temperature as a function of the concentration of water–glycerol mixture at which phase transformations occur. (Fig. 14 from [2])

Definitions by Luyet: AE: formation of small crystals or molecular groups, E: eutectic point, EB: formation of clusters, R: eruptive recrystallization, G glass transition.

The freezing time t_f can be estimated by Equation (1) [3]

$$t_f = \Delta J / \Delta T \rho_g \left(d^2 / 2\lambda_g + d / K_{su} \right) \quad (1)$$

where t_f is the freezing time, ΔJ the enthalpy difference between the initial freezing point and the final temperature, ΔT the difference in temperature between the freezing point and the cooling medium, d the thickness of the product parallel to direction of prevailing heat transfer, ρ_g the density of the frozen product, λ_g the thermal conductivity of the frozen product, and K_{su} the surface heat-transfer coefficient between cooling medium and the freezing zone.

The importance of vial selection, mentioned in Section Chemical Engineering Tasks in Industrial Freeze-Drying, also applies to freezing. The only two factors which can be influenced in Equation (1) are ΔT and K_{su}. K_{su} can vary by a factor of two (see Table 1), but lower values (e.g., 100) are also found. Quick freezing rates, one of the most important factors to reduce freeze-concentration and large crystals, can only be achieved by means of high K_{su} and large ΔT. The latter is limited by the brine viscosity/temperature in the shelves, e.g., to a minimum of –75 to –80 °C. This representation assumes that the heat transfer conditions from the brine to the shelf are optimum and more favorable than those from the shelf to the vial or tray (see Section Uniformity of Temperatures, Pressures, and Product).

Table 1. Surface heat-transfer coefficient, total heat-transfer coefficient, and thermal conductivity [29]

K_{su} from gases to a solid surface (kJ m^{-2}h^{-1} °C^{-1})	
free convection	17–21
laminar flow 2 m/s	50
laminar flow 5 m/s	100
K_{su} between the shelf of a freeze-drying plant and a product in vials or trays during freezing (kJ m^{-2} h^{-1} °C^{-1})	200–400
K_{su} between a liquid and a "solid" surface (kJ m^{-2} h^{-1} °C^{-1})	
LN_2 by drops on the product [33]	900
product drops in LN_2	up to 300
K_{tot} between the shelf of a freeze-drying plant and the sublimation front in the product contained in vials or trays under vacuum (kJ m^{-2} h^{-1} °C^{-1})	60–130
λ, thermal conductivity (kJ m^{-2} h^{-1} °C^{-1})	
λ_g, frozen product (ice) [34]	5.9–6.3
λ_{tr}, dry product [35-38]	0.059–0.29

The influence of the freezing rate on a 0.9 % NaCl solution can be seen by an electrical resistance measurement of the sample during freezing and warming in Figure 3 (3 °C/min) and Figure 4 (1 °C/min): at 3 °C/min the expected change at –21.7 °C is visible but mostly delayed to –30 °C (no equilibrium condition), during warming, as best seen in the first derivative, the mobilty of the ions increases relatively slowly over a temperature range from –50 to –20 °C, with an event at –30 °C; in Figure 4 crystallization is also delayed but to a abrupt change at –25 °C (A), and the event B during warming is very close to –21.7 °C. For pharmaceuticals the methods of freezing are limited: product in vials, seldom in trays, is frozen

on the shelves of the drying chamber, to reduce contamination risks; freezing by LN_2 is technically possible, but the expenditure is substantial. Product development should try to avoid this process. For food the freezing methods vary widely, as discussed in Section Food Plants.

Figure 3. Electrical resistance as a function of temperature for a 1 % NaCl solution, cooling rate 3 °C/min, warming rate 3 °C/min, and the first derivative d(log*R*)/d*T* (Figure 1.22.a from [7]).

Figure 4. Typical electrical resistance plot of 1 % NaCl solution with 1 °C/min cooling rate, event A at –24.5 °C during cooling, event B at –21.8 °C during warming. (Figure 1.22.2b from [7]).

2.2. Main Drying

Sublimation of ice during main drying (MD) is mostly governed by heat transfer to the sublimation front of the ice with temperature T_{ice} and the transport of the water molecules from the ice front through the dried product is the second factor which influences the main drying time t_{MD} for product with layer thickness of less than ca. 2 cm in the range of 10 to 20 %. The main drying time t_{MD} can be estimated by Equation (2) [4]

$$t_{MD} = (\varrho_g \zeta_w (LS) \Delta m d) / T_{tot}\{(1 K_{tot}) + (d/2\lambda_g) + [d/2(LS)b/\mu]\} \quad (2)$$

where ϱ_g is the density of the frozen product (kg/m^3), ζ_w the fraction of water in the initial product (kg/kg), LS the sublimation energy (2.805 kJ/ kg), T_{tot} the temperature difference (T_{sh}–T_{ice}), K_{tot} the total heat transmission coefficient from the shelf to the sublimation front of the ice, λ_g the thermal conductivity of the frozen product, *d* the thickness of the layer (m), Δm the fraction of frozen water = 0.9 kg/kg, and *b*/ μ the permeability (kg h^{-1} m^{-1} mbar^{-1}) for water vapor through the dried product.

In this equation the following simplifications are made:

- The layer is infinite; energy is only transmitted from the shelf to one side of the layer.
- The vapor is only transported from the ice front through the porous dried layer.
- The frozen layer is not porous.
- Heat transport in the already dried layer is neglected.

The error resulting from the last assumption at T_{tot} = 100 °C is ca. 4 %, and at T_{tot} = 50 °C ca. 2 %.

Similar to the freezing time equation one can influence the drying time of a given product by two factors: the temperature difference T_{tot} (T_{sh}–T_{ice}) and K_{tot}, the total heat transmission coefficient from the shelf to the sublimation front of the ice.

To calculate T_{tot}, T_{ice} must be known. It cannot be measured directly by sensors (see Section Barometric Temperature Measurement (BTM)), but by barometric temperature measurement (BTM). T_{ice} is not only necessary for estimating t_{MD}; it is also the most critical parameter in MD. T_{ice} is the equilibrium result of the energy transported to the ice front and energy used to sublime the ice. The heat supply and the sublimation of the ice depend on two main factors: The pressure in the chamber (p_{ch} or p_c) and the temperature of the shelves T_{sh}; however, the structure of the ice, the pressure difference between the chamber and the condenser which transports the sublimed ice, and the number of vials in the charge have more or less measurable influences, T_{ice} also supplies certain information about the condition and the structure of the product. Figure 5 and its legend show: collapse of the product is clearly marked by T_{ice}; lowering of T_{ice} (from plot 2 to plot 3) reduces the mobility of the molecules also in the concentrated inclusions; freezing in LN_2 (plots 4 and 5) produces a more uniform mannitol product, which can be dried without the abrupt changes of T_{ice} in run 2 at the same temperature as in plot 2. A lower T_{ice} (4 °C lower, run 5) does not prolong the first 10 h of MD. The delay of ca. 1 h in the next 10 h is due to the delayed equilibrium after T_{sh} has been raised. Figure 6 shows an other method of T_{ice} analysis: all T_{ice} measurements of one run are analyzed for the frequency distribution. The data of Figure 6 show the result of 5 runs (b represents 2 runs). The conclusions are: freezing of egg albumin (a) on the shelves of the plant leads to a fairly uniform structure, the distribution of T_{ice} data is regular (more data might improve this picture), the standard deviation (sd) of the average (av) is small (ca. 0.1 °C); (b) freezing in LN_2 without thermal treatment (see Section Methods of Structure Analysis) results in a larger sd, a frequency curve somewhat extended to lower T_{ice} meaning some preference for small

crystals and some differences between two runs with the same data, the dotted plot having a larger fraction of small crystals.

Figure 5. T_{ice} as indicator of the frozen structure of a 10 % mannitol solution, d = 10 mm. (Fig. 2.89 from [7]).

Runs 1 to 3: Product frozen in vials on the shelves to below –45 °C.

Run 1: sublimation rate too high for the possible water–vapor transportation, T_{ice} rises, product collapses, T_{ice} is irregular. Run 2: T_{sh} 0 °C, p_c 0.15 mbar, av T_{ice} –34.9 °C, sd 0.65 °C, product contains highly concentrated inclusions between ice crystals; depending on the position of the sublimation front, T_{ice} changes abruptly with the amount of concentrates being dried. Run 3: T_{sh} –5 °C, p_c 0.08 mbar, av T_{ice} –37.2 °C, sd 0.7 °C; due to lower T_{sh} and p_c the mobility of water molucules in the concentrate is reduced. In the first 6 h or so T_{ice} is a little higher than av; inclusions near the surface from freeze concentration are dried, after which the structure becomes more uniform, as indicated by a lower temperature of the ice. Runs 4 and 5: Product frozen in LN_2 and loaded on shelves at –45 °C, T_{sh} is raised at 10 h to +10 °C. Run 4: T_{sh} and p_c as in run 2, av T_{ice} –35.1 °C, sd 0.50 °C, after 11 h –34.5 °C, sd 0.6 °C. Run 5: T_{sh} and p_c as in run 3, av T_{ice} –39.1 °C, sd 0.22 °C, after 12 h –37.0 °C, sd 0.33 °C.

Figure 6. Frequency distribution of T_{ice} in 5 runs (2 runs together shown in b) (Fig. 1.78.2 from [7]. Data in Table 2.)

Table 2. Data of the runs in Figure 6

	EA*	EA	EA + 0.9 % NaCl	Pharmaceutical
Code in Fig. 6	(a)	(b)**	(c)	(d)
Cake thickness (mm)	20	20	20	20
Freezing method	shelf (sh)	LN_2	LN_2	shelf
T_{sh} (°C)	–5	20	20	0
P_c (mbar)	0.1	0.3	0.1	0.07
Average T_{ice} (°C)	–41.1	–29.2	–37.3	–42.2
sd (°C)	0.18	0.3	0.3	0.6

*Egg albumin.
**Two runs are shown in Fig. 6b with the same data, showing that LN_2 freezing without annealing can lead to slightly different structures and therefore slightly different T_{ice}.

The addition of NaCl and freezing in LN_2 (c) does not change the shape of the plot significantly compared with (b). The pharmaceutical product in (d), frozen on the shelf, does not have a uniform structure; if the dry product must have a more uniform structure, it should be frozen in LN_2.

2.3. Transition from Main to Secondary Drying (SD)

Temperature rise, pressure decrease, simultaneous measurement of pressure by thermoconductivity and capacitance gauges, and change in water vapor pressure by specific instruments are used to indicate the end of main drying. The many methods discussed show that all of them are not satisfactory to mark the end of the ice sublimation quantitatively.

As can be seen in Figure 5 and, in more pronounced form in Figure 7, average T_{ice} data are very constant as long as enough ice is available to fill the chamber with saturated water vapor after the valve between chamber and condenser has been closed; when the remaining amount of ice is unable to fulfil this condition, T_{ice} becomes systematically lower. The decrease in T_{ice} can be used to change the operating conditions from MD to SD, e.g., at maximum $T_{ice/n}$ = –1 °C or at maximum $T_{ice/n}$ = –3 °C (maximum $T_{ice/n}$ is defined as the maximum average T_{ice} of all T_{ice} measurements).

Figure 7. T_{ice} as a function of drying time. (O), (X): Measurements and repetition with the same product and the same process data; (•): Another product with other process data. 1) Average T_{ice}; 2) Standard deviation of T_{ice}; 3) Maximum $T_{ice/n}$ for o and × identical –22.53 °C; 4) Maximum $T_{ice/n}$ –1 °C, 4′) Maximum $T_{ice/n}$ –2 °C, 5) maximum $T_{ice/n}$ –3 °C. Maximum $T_{ice/n}$ = maximum of the average T_{ice} during MD (Fig. 6 from [5])

2.4. Secondary Drying (SD)

The desorption of the remaining water from the solids is called secondary drying. The moisture sorption behavior is often studied, e.g. by Fakes et al. [6] for mannitol, anhydrolactose, sucrose, D-(+)-trehalose, and dextran 40. The desorption process can be monitored by measuring the water desorption rate (DR), the desorbed amount of water in % of the solids of the product per hour (Equation 16a from [7])

$$\mathrm{DR} = 2.89 \times 10^2 \, (V_{\mathrm{ch}}/m_{\mathrm{fest}})(\mathrm{d}p/\mathrm{d}t) \tag{3}$$

where V_{ch} is the chamber volume (L), m_{fest} the mass of solids (g), dp the pressure increase (mbar), dt the measuring time for pressure increase (s). (By using 22.4×10^3 mbar L corresponding to 18 g H_2O, mbar L can be converted into grams).

Figure 8 shows the DR data of a 10 % sucrose solution with different number of vials, different freezing methods, and different T_{sh}. In all runs d = 10 mm and p_c = 0.15 mbar. The figure shows how the DR data sensitively reflect the various influences of freezing and MD process data: Run 1: T_{sh} too high, the product collapses; Run 6: longest t_{MD} (T_{sh}–T_{ice} = T_{tot} 7 % lower than in run 5), shortest t_{SD}, but dW = 1 % is practically reached in the same time as in run 5 (not shown in Fig. 8), since DR in run 6 during SD is larger than in run 5. Runs 3 and 4 are for LN_2 freezing, which has no influence on t_{MD}, but the desorption behavior is different, as plots 3 and 4 and the times for DR = 1 and 0.3 %/h show. Furthermore, one can see that the amount of uncrystallized water is larger for quick cooling: between DR 0.5 and 0.6 %/h the desorption is slower and the plot flatter. If the number of vials is increased and T_{tot} is decreased to 31.2 °C, as in run 2, t_{MD} increases, in agreement with Equation (2).

Figure 8. DR as a function of time with various process parameters (Fig. 2.91 from [7].)

Plot no.	Vial no.	FM[a]	T_{sh},[b] °C	T_{ice}, °C	t_{MD},[c] h	DR,[d] %/h	dW,[e] %	$v_{Tsh}/20$,[f] °C/min	t_{SD},[g] h
1	300	W	+30	product collapsed					
6	400	W	0	–32.3	10.15	14.3	14.6	0.12	4.45
5	100	W	0	–34.5	9.15	12.5	15.0	0.10	5.85
3	100	LN_2	0	–33.8	9.1	15.9	15.6	0.06	6.5
4	100	LN_2	0	–34.1	9.3	16.4	16.1	0.07	6.8
2	300	W	–5	–33.8	11.1	15.6	18.0	0.10	6.9

[a] FM: freezing method: W: vials charged on shelves at room temperature and cooled with the shelves, LN_2: product frozen in vials cooled by LN_2.
[b] T_{sh} = shelf temperature during main drying.
[c] t_{MD} = main drying time.
[d] DR (%/h): time in hours in which 1.0 %/h is reached.
[e] dW (%): time (h) in which the desorbable water content reaches 1 %.
[f] v_{Tsh20} / rate of temperature increase to 20 °C.
[g] t_{SD} secondary drying time (dW = 1 %).

If the DR data shown in Figure 9 are integrated over time the residual moisture content can be calculated in percentage of solids, as shown in Figure 10. The product is a 10 % albumin solution, filling height 10 mm, except for plots 5 and 6 (filling height 20 mm); T_{sh} in all plots 20 °C. In plots 1, 2, 3, and 5 the product was frozen on shelves, 4 and 6 in LN_2. Main drying in plot 1 at 0.5 mbar, all others at 0.3 mbar. In Figure 10 plots 2 and 3 are omitted for clarity. Runs 1 and 4 differ by the freezing method but mainly by the operating pressure p_c and therefore by T_{ice} –25.7 °C (1) and –28.8 °C (4). In spite of the smaller T_{tot} for run 1 (ca. 7 %), the pressure-dependent increase in K_{tot} (ca. 57 %) reduces the time to dW = 1 % from ca. 8.5h to ca. 5.7h (66 %). The pressure dependence below 0.1 mbar decreases.

Figure 9. Desorption rates (DR) as a function of total drying time (Fig. 4 from [25]). 100 vials filled with 10 % albumin solution, with different freezing methods, different p_c, and different product thickness. Parameter: 1) 0.5 mbar (W), 2) 0.3 mbar (W), 3) 0.3 mbar (C) 4) 0.3 mbar (LN_2), 5) 0.3 mbar (W), 20 mm, 6) 0.3 mbar (LN_2), 20 mm.

Figure 10. Residual moisture content dW as a function of time (Fig. 5 from [25]). 100 vials with 10 % albumin solution, with different p_c, different freezing methods, and layer thickness as parameter. 1) 0.5 mbar (W), 4) 0.3 mbar (LN_2), 5) 0.3 mbar (W), 20 mm, 6) 0.3 mbar (LN_2), 20 mm.

The DR and dW data monitor not only SD, but provide also information about the freezing rate, the amount of unfrozen water which could crystallize under certain conditions and which would otherwise delay reaching low dW values or make this practically impossible.

2.5. Packing and Storage

Vials as product containers are placed on the shelves with rubber stoppers already in a “holding” position, in which the water vapor can pass through canals in the stoppers from the inner of the vials to the drying chamber. The “packing” of the product takes place in steps: The stoppers can be pushed into the closed position under vacuum, or the chamber and therefore the vials are filled with a dry, sterile gas at a certain pressure, and then the vials are closed. The documented sterility of the gas is a technical problem (see Section For Pharmaceutical Products). The closing of several tens of thousands of vials requires many tons of pressure. The chemical engineering task with the stoppers is twofold:

1. During freezing the stoppers may shrink and slide into closed position, no drying is possible, and the product in such vials will melt. The canals must be large enough for water vapor flow without undue flow resistance, but they have also to be large enough to evacuate the vial parallel to the chamber, otherwise the overpressure in the vial will blow the stopper from the vial, the vial cannot be closed, and the stopper may impair the order of other vials and their closing. The stoppers and the vials have to be tested under these different conditions: on cold shelves, during evacuation (which speed is tolerable), and on heated shelves during SD.
2. The stoppers are steam-sterilized and absorb water during this process, which must be removed; otherwise, it will diffuse into the product during storage. During sterilization optimum stoppers take up ca. 1 % of water. Even with a stopper weight of only several grams, the amount of water can be 0.1 to 0.05 g. The amount of product in a vial will often be 1 g or less. 1 % residual moisture is then 0.01g. The equilibrium between water in the stopper and the product depends on the storage temperature and the sorption behavior of both. Fortunately, a certain amount of water in some stoppers is strongly bound to the stopper material (WANG et al. [8]) and can not desorb from the material at 100 °C, which is well above any storage temperature.

The time of safe storage of all pharmaceutical product depends on the storage temperature and the possible reactions of the product with water or within its own components. The water could defuse from the stopper to the product or be freed from the product if it is transformed from the amorphous into the crystal phase. This devitrification temperature T_g of glass-forming anhydrous carbohydrates varies from 120 °C for trehalose to, e.g., 77 °C for sucrose; it decreases with increasing water content of the dried product. On the other hand, RM can not be too low, since missing water molecules in a protein will cause its denaturation. The reactions between various components of the product or within one component do not stop at T_g; HATLEY and BLAIR [9] describe that this happens only at a temperature they call zero-mobility temperature T_0, which for trehalose is 44 °C and for sucrose 3.5 °C.

The packing and storage of food is governed by the large quantities to be handled (up to many tons of dry product per day) and the nonsterile conditions. The freeze-dried food is as hygroscopic as pharmaceutical products. Foods are freeze-dried in trays, which have to be vented in the plant with a very dry gas, often N_2, sometimes air, depending on the oxygen sensitivity of the product. Dry gas means a due point corresponding to the end pressure of drying, e.g., for 0.02 mbar, the due point of the gas should be ca. –55 °C. Once the pores of the dry product are filled with dry gas, some products can be handled for a short time in normal air, and often dry air is preferred. The container for long-term storage must be leak-tight (e.g., glass with a glued-on foil together with a screwed-on cover for protection or a can). A maximum water content of the product is required, this can be, e.g., 2–3 % or less than 1 %.

[Top of Page]

3. Temperatures and Pressures

3.1. Barometric Temperature Measurement (BTM)

During freezing temperature sensors can be used, since they are in relatively good and constant contact with the product. This is completely different during MD, since the ice front moves through the product and the product can contain ice or is already dry. The decisive factor is the temperature at the moving sublimation front, denoted T_{ice}. It can be measured by

the equilibrium water vapor pressure of the ice, the saturation vapor pressure p_S. If the valve between chamber and condenser is closed, the pressure in the chamber will rise to the equilibrium and this can be converted into the temperature of the ice (Table 3).

Table 3. Equilibrium water vapor pressure of ice (p_S) and related specific density of the vapor (ρ) (From [31])

t°C	p_S mbar	ρ_D g/m^3
– 70	$2.615 \cdot 10^{-3}$	$2.789 \cdot 10^{-3}$

This pressure measurement should last < 3 s to avoid a temperature increase during the measurement time (sublimation decreases if the pressure approaches equilibrium, but heat transfer remains). To measure the increase in pressure accurately enough, the pressure should be recorded at a rate of 100 Hz. This can only be done by an automated system, and a computer can calculate the first derivative to determine the change in the slope of the pressure rise, which marks the equilibrium pressure, as shown in Figure 11. Besides the time limit two conditions for this measurement have to be fulfilled:

1. The amount of ice sublimed in the measuring time must exceed a certain ratio in relation to the chamber volume, since the accuracy of the pressure gauge has a certain limit (Eq. 4)

$$V_{ch}\mathrm{d}p/\mathrm{d}t < m_{H_2O}/t_{MD} \quad (4)$$

where V_{ch} is the chamber volume (L), dp = p_s–$p_{H_2O,ch}$ (mbar) the pressure rise during the measuring time, dt the time (s) until p_s is reached, m_{H_2O} the mass of water to be sublimed during MD, and t_{MD} the time of MD (s).

Figure 11. Pressure rise as a function of time. 1) Pressure rise in the chamber after the valve is closed; 2) First derivative of 1). The maximum of 2 is reached at 2.14 s, and the related equilibrium (saturation) vapor pressure is p_s = 0.286 mbar corresponding to T_{ice} = –32.7 °C. (Fig. 2 from [5].)

2. The leak rate of the chamber must be so small that the pressure increase due to this leak is small compared with the pressure rise due to the water vapor equilibrium pressure; e.g., in a chamber of 2000 L the pressure rise due to BTM is 4.3×10^{-3} mbar/s, corresponding to 8.6 mbar L/s; if the pressure rise due to the leak must be small (e.g. 1 %), the leak rate should not exceed 8.6×10^{-2} mbar L s^{-1}.

The pressure gauge in a freeze-drying plant should always be based on the capacitve (CA) and not on the thermal-conductivity (TM) principle. The thermal conductivity of a gas in a certain pressure range depends on the pressure but also on the gas type. In freeze-drying one can expect 90 % or more water vapor at the beginning of MD and less than 10 % water vapor at the end of SD. The reading of a TM calibrated in air at 0.1 mbar would be 0.05 mbar if the gas were pure water vapor. Furthermore the reproducibility of a TM is given by manufacturers as 20 % in the range between 10^{-3} and 10^{-2} mbar and as 15 % above 10^{-2} mbar. This leads to a calculated error in T_{ice} of ±1 °C, which in itself is too large, and the resuting uncertainty in the gas mix makes a TM unacceptable for freeze-drying.

The leak–rate measurement of a production plant should be done before each run. An undetected leak is a risk that can most likely not be repaired during a run and may ruin the total charge. The leak rate measurement and the hunting of leaks is described in section 2.2.9 of [7]. If the leak rate of a plant is measured at fixed time intervals, as described, it is possible to shorten the procedure before each run:

1. The history of the plant before the test must be standardized, e.g., the test is always done after sterilization of the plant, and its temperatures are all in the same range, e.g., 40 °C.
2. The evacuation time of the plant is recorded from atmospheric pressure to the operating pressure at the end of SD (e.g., 10^{-2} mbar). If this plot is within agreed tolerances at the end of the evacuation, one can assume that the plant is leak tight enough for the next run. Such a test should be done after sterilization since it insures not only sufficient leak tightness after the temperature and pressure changes, but also proves that no measurable amounts of water are hidden anywhere in the plant.

3.2. Pressure During Secondary Drying

The desorption of water from the solids depends for a given product only on the temperature, provided that the water vapor pressure in the chamber does not hinder the diffusion of the water vapor from the product into the chamber. The desorption isotherms describe the equilibrium between vapor pressure and the water content of the solid at a given temperature. In Figure 12 three desorption isotherms of a pharmaceutical product are given.

The water vapor pressure in the chamber should be small compared with the equilibrium vapor pressure, and the pressure of the permanent gases must be smaller than the vapor pressure in the chamber to facilitate the diffusion of the water vapor. The consequences for the pressure in the chamber (product as in Fig. 12) are, e.g., at an end temperature of 20 °C: to reach RM 0.2 % a water vapor pressure in the chamber $p_{H_2O,ch}$ = 2×10^{-3}mbar and for RM 2 % $p_{H_2O,ch}$ = 1×10^{-2}mbar are required; at 40 °C under the same pressure conditions RM 0.1 % and 0.8 %, respectively, can be reached. The final RM depends on the isotherms, which can only be measured with a certain effort in equipment and time. There is no relationship between p_c during MD and $p_{H_2O,ch}$ at the end of SD, but experience shows that the pressure during SD with T_{sh} in the range from 30 to 50 °C should be 10 % or more lower than p_c. Besides the pressure, the time to reach the desired temperature in the product depends on the thermal conductivity in the dried product, which can vary by 30–40 %, depending on the freezing method, for the same product (Fig. 8). For foods λ_{tr} can vary by a factor of 6. Since the desired

RM depends on the product temperature, the SD time depends not only on the pressure but also on the thermal conductivity of the dried product.

Figure 12. Desorption isotherms of the residual moisture content (wt %) as a function of water–vapor pressure. 1) 20 °C, 2) 40 °C, 3) 60 °C. (Fig. 1.85.6 from [7].)

Depending on the maximum tolerable product temperature and the desired RM for food, it can be possible that the required RM is reached without lowering the pressure for desorption or secondary drying. This means that temperature is high enough to reach the desired RM without lowering the pressure.

3.3. Water–Vapor Flow

During main drying the heat transfer to the sublimation front determines t_{MD}, but the plant must be designed to permit transport of the water vapor from the chamber to the condenser. The water vapor flow in the pressure range of freeze-drying, mainly from 0.8 to 0.01 mbar, is neither clearly viscous nor molecular; the mean free path of water vapor at 0.01 mbar and –40 °C is ca. 3.5 mm. The flow can be estimated from Fig. 13 (for details, see section 1.2.4 in [7]) which reflects some simplifications: The flow density is calculated for straight connections between chamber and condenser with the length to diameter ratio *l*/*d* as parameter. This does not account for a valve in the connection or for a bend. If chamber and condenser are flanged together and a mushroom valve is installed in the condenser, as in Fig 21, one can expect this configuration to have the same flow density as a connection with *l*/*d*≈1.6. A bend is characterized not by its geometrical dimensions, but by the “resistance” length, which is at least twice the actual length and can be five times as high; this depends strongly on the design and the pressure range of operation. For any production plant the flow density as a function of operating pressure is of vital interest, it should be measured once and than be used for the transfer of processes from a pilot plant to production. Example: In a pilot plant with *d* = 25 cm and *l*/*d* = 1.6 the vapor flow was 2.9 kg/h at 0.2 mbar and 0.37 kg/h at 0.06 mbar, showing that the plant is used at about 75 % water transport capacity (Fig. 13), and the flow density decreases more than linearly with pressure. The production plant has *d* = 80 cm; can it be operated under the same conditions with 25 times larger load than the pilot plant? At full flow capacity and *l*/*d* = 1.6 one can expect 40 kg/h at 0.2 mbar and 5 kg/h at 0.06 mbar, which allows only a loading of 13.5 times that of the pilot plant; even a valve with a large diameter of 1.1 m would only allow ca. 20 times the loading of the pilot plant. If the production plant is designed differently and has *l*/*d* = 5.0 (which could happen with one 90° bend) the flow capacity is reduced for the 80 cm valve to ca. 29 kg/h at 0.2 mbar and 2.5 kg at 0.06 mbar. With a larger *l*/*d* the decrease with pressure is more pronounced than with a smaller *l*/*d*. The measurement of the water vapor flow density is straight forward: a weighed amount of distilled water is filled (filling height ca. 12 mm) into the maximum possible number of vials, the water is frozen on the shelves to the minimum possible T_{sh}, and main drying is started for a given set of operating data, e.g., p_c = 0.15 mbar and T_{sh} = 20 °C. Drying is terminated when ca. 50 % of the ice has sublimed, the plant is vented, and the amount of water sublimed is determined by weighing. The weight loss divided by the time span after T_{sh} has been reached and the time of venting divided by the free area of the connecting tube between chamber and condenser is the flow density. This measurement is repeated at least at one or, preferably, two different pressures, e.g., 0.08 and 0.04 mbar. The three (two) measurements should be on one of the plots in Fig. 13, and *l*/*d* can be determined. If the resulting plot is to the left of the shown plots, *l*/*d* is larger than 5; nevertheless it can be used as the characteristic flow density curve of this plant.

Figure 13. Density of water–vapor flow (g cm^{-2} h^{-1}) as a function of p_{ch} with jet flow (1) and *l*/*d* = 1 (2), 1.6 (3), 2.5 (4), and 5 (5) as parameter. 4) and 5) are not plotted below 4 10^{-2} mbar, as these data depend strongly on design details of the plant. They should be measured if needed. (Fig. 1.89 from [7].)

3.4. Residual Moisture Content

The drying time and the storage capability depend on the residual moisture content (RM) of the dry product. The methods for measuring this water content vary from chemical extraction and desorption under different conditions to analysis of the near-infrared spectrum.

The gravimetric method was obligatory according to the FDA until a few years ago: The weighed product (more than 100 mg) is stored in a gas tight container at 20 or 30 °C together with P_2O_5 and repeatedly weighed until the weight becomes constant. The weight loss is the RM of the product.

In thermogravimetric analysis the product (min. 2 mg) is placed in a microbalance in a temperature-controlled oven, and the weight loss is determined either at a constant temperature (e.g., 40 °C) or during a temperature profile (e.g., 5 °C/min from 30 to 100 °C). The weight loss is the RM of the product. To detect temperature-induced decomposition of the product, a mass spectrometer can be added to identify the molecular mass of the desorbed or decomposed molecules.

The Karl Fischer method extracts the water from the product into methanol and determines the amount of extracted water by titration with the Karl Fischer solution. In automated equipment the iodine for titration is produced by electrolysis and the

required amount of iodine for the titration is calculated by Coulomb's law. About 10 µg of water can be measured. The method does not work if the water cannot be extracted by methanol or the product reacts with iodine.

Water molecules have characteristic lines in the near-infrared (NIR) spectrum. The intensity of absorption in these lines is a measure for the amount of water molecules per unit volume. This method can be applied repeatedly in a vial without opening it. Since other components can have absorption lines overlapping with those of water, the measured spectrum must be mathematically analyzed; it varies with changes in the concentrations of the components. A calibration of the spectrum for water content is therefore only possible for one product. Within certain limits [10] the method can be used to check a large number of vials with product; the sample is not destroyed by the test. All methods depend on the binding energy between solid and water molecules. The results with each method can but need not be different from each other. RM data should be given with indication of the method of determination.

All methods described above can only be used after the drying process is terminated and the vials or the food products are removed from the freeze-drying plant. To determine RM data during SD can today only be done by the measurement of DR and the integration of DR over time resulting in dW; depending on the product temperature (e.g., 20 °C) only very weakly bonded water molecules will desorb, while at 40 °C additional molecules can be removed from the product.

3.5. Uniformity of Temperatures, Pressures, and Product

As noted in Section Chemical Engineering Tasks in Industrial Freeze-Drying uniformity of production is an important task for chemical engineering in freeze-drying. In a conventional production freeze-drying plant the reasons for a nonuniform quality of the product can be

1. Different flows of brine through each shelf (e.g., 12 shelves connected to one supply tube)
2. Different heat-transfer coefficients from the brine to the shelf within one shelf due to different brine flows in parts of the shelves
3. Delayed temperature increases or decreases due to different masses to be heated or cooled in parts of one shelf.
4. Certain areas for water–vapor transport are too small compared with the necessary flows in that area (to achieve the *l*/*d* ratio of 1.6 mentioned above, all other critical areas should be large compared with the area of the connection between chamber and condenser); or, differently stated: the pressure differences in the drying chamber have to be small compared with the operating pressure. This criterion becomes more important with low operating pressures, e.g., below 0.1 mbar and decisive below, e.g., 0.06 mbar
5. Influences of the door and wall temperatures on the product during freezing and freeze-drying.

The first point can be checked and corrected by conventional means. The second and third reasons are more difficult to quantify, since it must be done when the shelves are loaded. One possibility is to combine this test with the flow-density measurement described in Section Water–Vapor Flow. One shelf is selected as the model shelf. Around the entrance and the exit of the brine several temperature sensors are soldered to the shelf, as well as around the borders and in the center of the shelf. Furthermore, temperature sensors are distributed in the water in the vials in the same arrangement as those on the shelf. All sensor data are recorded during freezing and main drying. The sensors on the shelf around entrance and exit of the brine should show temperature differences during heating or cooling of 1–2 °C and less than 1 °C when the temperature is kept constant. Between the average of the inlet and outlet sensors the temperature difference can be 2–4 °C during heating or cooling and less than 0.5 °C when constant temperature is reached. The data given are examples of measured values; they may vary with the design, but the principle remains: a few °C are tolerable during temperature changes, but during constant-temperature conditions the temperature difference should be smaller than 0.5 °C. These measurements take some time and they must be taken once for a new design of a shelf. However, the user should ask the manufacturer for the results of such tests. Only then can the shelf design be excluded as a reason for nonuniform product quality. The temperature measurements in the water/ice during freezing will basically have a larger range of variations, since the freezing rate depends mainly on the degree of subcooling, the number of nuclei per unit, and the growth speed of the crystals. These conditions are not identical in all vials. But the average (av) freezing rate and its standard deviation (sd) between the regions on the shelf have to be the same: e.g., the av rate and its sd of all vials on the border of the shelf should be similar to those of all vials in the center or to all vials near the entrance and exit of the brine in the shelf. If the data on the shelf are satisfactory but those in the water/ice are not as acceptable it can be concluded that the influences of the door and wall temperatures disturb the uniformity. This can be confirmed if the sensors in the ice during MD show different av temperatures in vials at the border than in the center of the shelf. The door and wall temperatures can be substantially different, especially at low or high temperatures compared with room temperature, as shown in Figure 14. The consequences of these temperature differences on the water content of the product in vials (Fig. 15) are more drastic than expected. Without any shielding the product on the borders of the shelf shrinks, and RM is much too high; with the aluminum shields this product does not shrink, but the RM in the border vials varies widely, and only with a temperature-controlled shield do all vials have a uniform RM. The data are from a pilot plant (ca. 1000 vials); in a production plant with a greater mass of steel in the chamber and especially with a small amount of solids in each vial, the influence can be substantially more pronounced. It is a task of chemical engineering during pilot plant runs to define the necessary means of shielding a product and its process.

Figure 14. Temperature distribution during freezing (4.5 h) and freeze drying (8 h). Each shelf carries a frame for radiation shielding. The design can be different depending on the kind of vials and the loading and unloading system.

1) Internal temperature of the wall of the chamber, 2) Internal temperature of the door, 3) T_{ch}, 4) T_{pr}, 5) Temperature on the inner side of the radiation shield.

Figure 15. Residual moisture content in three identical runs with different shielding between vials and walls and door(s). (Fig. 1.68.2 from [7].) In each run six groups of vials where formed (168 vials each). Rows 4, 5, and 6 were close to the door, and rows 1, 2 and 3 close to the back wall.

a) No shielding, b) Shielding by an aluminum shield placed on the shelf, c) Shielding by temperature controlled shields

Residual moisture content distribution in the three runs

Run	a	b	c
Shrunk product			
rows 1–3	10 vials	0	0
rows 4–6	13 vials	0	0
RM in shrunk product	7/21 %	–	–
	av 15 %, sd 6.2 %		
Product in center vials	0.9/1.1 %	0.6/1.0 %	–
	av 1 %, sd 1 %	av 0.85, sd 0.15	
Product in rows 1–6	–	0.9/4.5 %	—
		av 1.9 %, sd 1.6 %	
All vials	–	–	0.4/1.0 %
			av 0.72 %, sd 0.15 %

For food products the temperature accuracy may be less stringent, but the temperatures of the frozen product can be as low as –40 °C and the shelf temperature during part of MD may be as high as 100 °C, resulting in a temperature difference between wall and shelf of ca. 80 °C. The shelves in a food plant can be formed in such a way that they are themselves the shields between wall and product. Such a solution is difficult in a pharmaceutical plant where easy cleaning, no corners, and rinsing of all water are “must” criteria.

[Top of Page]

4. Structures of Frozen and Dried Products

4.1. Influence of Freezing Method and Excipients

As shown in Section Freezing freezing rate, end temperature of freezing, excipients, and thermal treatment (see Section Methods of Structure Analysis) control the frozen structure. During drying this structure can only deteriorate by softening, collapse in micro-areas, collapse in total, modification of its amorphous structure, change from an amorphous structure to crystalline, growth in crystal size (recrystallization), and melting.

Most of these processes or events can be attributed to a certain temperature-time profile, a characteristic temperature, or a typical product behavior. In trying to generalize the influence of freezing, it becomes clear that many details contradict each other, such as fine crystal structure, all water crystallized, and no freeze-concentration of solids in water. There is only one general rule: If the freezing process and the events after the end of freezing and the beginning of drying are not well understood, the drying process can not be successfully engineered. An impressive example is given by BAKALTCHEVA and REID [11] with the drying of red blood cells (RBCs), a problem tried again and again over several decades. First one must find a cryogenic and drying protective agent. To stabilize proteins it is known, that sugar molecules can replace water molecules which are not removed during drying. Glycerol has been used to stabilize RBCs, but cannot be used in pharmaceuticals. The authors used adonitol, a polyol with similarities to glycerol, as protective agent in which they kept the cells for 12–14 h at 4 °C. Then they were frozen in a solution of 250 mM adonitol, 12 mM sodium phosphate dibasic, 2.9 mM sodium phosphate monobasic, and 20 wt % albumin, either on a precooled shelf at –30 °C with a cooling rate of 2.5 to 5 °C/min or in LN_2 at a rate of 75 °C/min. The LN_2-frozen product was kept for 48h at –30 °C. Both products were thawed for 10 min in a water bath at 37 °C. The survival rate after freezing on the shelf was 15 %, and after freezing in LN_2 80 %. From additional tests (not shown) the authors concluded:

1. For an optimum survival of RBCs a freezing rate of ca. 100 °C/min is necessary.
2. The damage to the LN_2-frozen cells is mainly a result of warming the cells from –196 °C to –30 °C (author’s note: crystals have time to grow and destroy the cells). The solution: Freezing in LN_2 down to only –30 °C and immediate freeze-drying at –30 °C (author’s note: no homogeneous crystallization of water at ca. –40 °C).

This example demonstrates the main problems of freeze-drying sensitive cells: Some water must be exchanged against a noncrystallizing agent, which at the same time delays the crystallization of the remaining water.

The freezing must be fast to attain the amorphous phase of water without crystallization or at least with only a limited amount of microcrystals. The sublimation time at –30 °C is not long enough to permit a change from the amorphous to the crystalline phase at the concentration of the excipients used. As shown in Figure 1 phase transition is a function of temperature, concentration, and time. Another example by MA et al. [12] shows the interdependence of various steps in the freezing and freeze-drying of tumor necrosis factor (TNF-MAb). The formulation consists mainly of 20 mg/mL TNF-

MAb, 10mg/mL maltose as stabilizing amorphous sugar, and 20 mg/mL glycin as bulking agent. The T_g of the product with in completely crystallized glycin was –42 °C. A process with heat treatment (see Section Methods of Structure Analysis) was developed: Cooling the product slowly (<1 °C/min) to –45 °C, slowly warming to –25 °C, and cooling the product back to –45 °C. The thus-frozen product could be dried at a T_{ice} of less than –25 °C (instead of below –42 °C), and in SD an RM of ca. 0.5 % could be reached in a normal desorption process, as confirmed by measurement of the desorption isotherm.

4.2. Methods of Structure Analysis

Structures of frozen and freeze-dried products are critical for the freeze drying process and the storage capability. Therefore, several methods have been developed to study them. Cryomicroscopy uses a cell for the sample which can be cooled, heated, and evacuated. The microscope is used to observe the frozen, the drying, and the dried product. Figure 16 was taken during quick cooling at ca. –25 °C, Figure 17 during the first warming process from –50 °C to ca. –35 °C and Figure 18 during the second cooling process at –55 °C. In Figure 16 the crystals (dark) are mostly uniformly distributed between the amorphous, concentrated solids (lighter color). In Figure 17 the crystals have grown, and some water from the concentrate has crystallized. In Figure 18 the boundaries between crystals and glass inclusions are more clearly visible, especially in the upper right corner; here the product was heat treated by warming to –35°C after the first quick cooling and brought back to –55 °C before drying; such a process is called thermal treatment (TT). A cryomicroscope permits a freezing and drying process to be followed visually. Crystal growth, softening of the structure, collapse, and melting can be recognized. The very thin layer is difficult to freeze slowly, and the behavior of the thin layer may be different from that of a 10 or 20 mm cake; nevertheless, cryomicroscopy is a very helpful tool for understanding the behavior of a product during freezing and freeze-drying. The scanning electron microscope is very effective for visualizing the structure of the dry product and its change during storage. Figure 19 shows the effect of freezing rate (a and b), collapse (c), and shrinking (d) on the structure of a product.

Figure 16. Cryomicrograph of a pharmaceutical product frozen at a rate of ca. 4 °C/min. During cooling at ca. –25 °C (Steris GmbH, Hürth, Germany)

Figure 17. After cooling to –54 °C and thermal treatment (TT) at –36 °C (Steris GmbH, Hürth, Germany)

Figure 18. After cooling again to –55 °C (Steris GmbH, Hürth, Germany).

Figure 19. Photographs of a 1 % lactose solution by scanning electron microscopy. a) Frozen at 1 °C/min, b) Frozen at 150 °C/min, c) Collapsed dried trehalose solution from the bottom of the product, d) The same product shrunk after 6 months of storage at +20 °C with too high an RM and too high a storage temperature. (From [30].)

The other methods mainly used to study the freezing process are measurement of the electrical resistance (ER) as a function of temperature, thermomechanical analysis (TMA), differential scanning calorimetry (DSC), and nuclear magnetic resonance (NMR).

ER equipment is relatively inexpensive and straightforward to operate. Interpretation often requires experience with various products; its advantages are samples comparable with production freeze-drying and the possibility to simulate freezing on the shelf, as shown in Figure 20. In the lower part the 1st derivatve d(log$R$)/dT is shown, which greatly improves the visibility of events. In Figure 20a the sample vial with the product was immersed in the cooling medium, while in Figure 20b the cylindrical part of the sample vial was isolated by layers of plastic foils to simulate heat transfer from the shelf to the bottom of the vial. In Figure 20a the crystallization energy can be more quickly removed, part of the water crystallizes at around –10 °C, but another part solidifies without crystallization; this part softens during warming at event 1 and permits crystallization at event 2. In Figure 20b freezing takes place in two steps closer to equilibrium and events 1 and 2 can not be detected during rewarming. Conclusion: If this product is frozen on the shelf at 1 °C/min thermal

treatment to crystallize remaining water is not necessary. In thermal treatment or annealing after first freezing a product is heated to a temperature at which the water molecules can move enough to diffuse to existing crystals or nuclei; liquid water which may not have crystallized during the first cooling can crystallize during warming or the subsequent second cooling. Heat treatment can also be used to crystallize other ingredients which did not crystallize under the conditions of the first cooling. More details and applications are given in [7, section 1.1.5.1].

Figure 20. a) Electrical resistance of a pharmaceutical product as a function of temperature during cooling at 1 °C/min and rewarming at 3 °C/min. Heat-transfer medium surrounds the sample vial. b) Measurement of the electrical resistance as in (a), but the wall of the vial is insulated by a plastic tape up to the filling height of the product. Therefore, the heat is mostly removed through the bottom of the vial. (From [13].)

Differential scanning calorimetry (DSC) compares two different heat flows: one to or from the sample to be studied, and the other to or from a substance with no phase transitions in the range to be measured, e.g., glassmaking sand. The development of DSC equipment with a low heat capacity and quick response times has made it possible to modulate the normal temperature ramp by a sinusoidal temperature oscillation, a technique known as modulated DSC (MDSC). By Fourier transformation the total heat flow can be separated into reversing and nonreversing “kinetic” components. The reversing heat flow especially reveals glass transition events, which may be difficult to identify in the total heat flow signal or overlap with other nonreversing events. The reversing flow signal can be used to calculate heat capacity and its variation. The nonreversing component represents kinetic events such as crystallization and enthalpic relaxation; an example of MDSC is given in [14]. An other method to differentiate between reversible and the irreversible heat flow is the StepScan DSC [15]. The precondition for its use is a DSC system with a power compensation: sample and reference material are held in two separate calorimeters, each with its own heating elements. Both systems are maintained in equilibrium condition. The amount of energy to keep the equilibrium is directly proportional to the energy change in the sample. The power compensation system measures heat flows, whereas normal DSC systems measure temperatures. The StepScan method applies heating (e.g., 10°C/min) over a small temperature increment (e.g., 1.5–2 min), holds this temperature for a short time (e.g., 30 s), and calculates the heat capacity at that temperature. The irreversible or kinetic part of the total heat flow represents the “slow” processes which take place during the scan: enthalpic relaxation, crystallization, and melting. The two DSC methods permit the energy balances of the events to be quantified and the amount of product involved to be estimated. They measure changes in heat capacity (structural changes in amorphous products), and they can generally differentiate between irreversible processes (e.g., crystallization, melting) and reversible processes (e.g., glass transitions). The data obtained are quite accurate, but the equipment is much more expensive than an ER instrument; since the product quantities are very small, events in a product volume which may be several orders of magnitude larger and exposed to different heat-transfer conditions must be analyzed with regard to these two aspects.

Nuclear magnetic resonance (NMR) can be used to determine whether water is bound to other molecules (e.g., proteins) and therefore can not crystallize, how the collapse temperature T_c is influenced by unfrozen water, and the changes in a glass of highly concentrated solutions during warming from low temperatures below and above T_g. For example, YOSHIOKA et al. [16] studied the mobility of protons by NMR spectroscopy in freeze-dried bovine serum albumin (BSA) and gamma-globulin (BGG) and its relation with susceptibility to aggregation. The increase in spin–spin relaxation time t_{SR} of protons in BSA and BGG was strongly related to the water content in the range of 0.2 to 0.5 g water/g protein in both products and increased susceptibility to aggregation.

Thermomechanical analysis (TMA) has been used to measure the expension of the sample during freezing and warming. It has been helpful in explaining the breakage of vials during the warming of frozen mannitol solutions. Mannitol solutions above –25 °C expand ca. 30 times more than standard type 1 flint glass.

5. Industrial Freezing and Freeze-drying Installations

5.1. For Pharmaceutical Products

Sterility of the equipment and sterile handling of the product, which today is not sterilized as a finished product, are the compelling guidelines for the design of plants, the freezing and drying process, and packaging. Cleaning and sterilization of the plants is part of the total process and must be validated and documented during each run; both can only be fulfilled if the operations are mechanized and automated. They are therefore described in Section Process Automation. The freezing of pharmaceutical products in vials (or seldom in trays) is mostly done on the shelves of the plant. Freezing in LN_2 is technically possible and used, e.g., to freeze thick layers of product (35 mm) at high rates (> 10 °C/min). The mechanical engineering has to take care of the following special tasks in the design of freeze-drying plant: Water and condensate must freely flow from all parts of vessels and pipes; dead-end piping should have a minimum ratio of l/d = 2, and if possible 6; the door seal has to avoid condensate at the lower area of the door. The chambers are mostly cube-shaped with five critical parts: The door(s), the closing system for the stoppers, the shelves, the connection between chamber and condenser, and the venting system for the plant. The condenser is usually cylindrical and contains as main parts: the valve to shut off the chamber, the surfaces to condense the water vapor, the water drain, and the connection to the vacuum pumps. Figure 21 shows a schematic of a freeze-drying production plant with ca. 20 m^2 shelf area.

Figure 21. 1) Trolley for loading and unloading, 2) Vials in trays, 3) Sterile room, 4) Door, 5) Cleaning in place (CIP) system, 6) Pressure plate for closing stoppers with hydraulic system, 7) Water drain, 8) Water ring pump, 9) Heat exchanger for the brine, cooled by LN_2, 10) Heat exchanger for the brine, cooled by water (+20 °C), 11) Heat exchanger for the brine, electrically heated, 12) Brine (heat-transfer medium) circuit, 13) LN_2 inlet, 14) N_2 gas outlet, 15) Water for defrosting, 16) Roots vacuum pump, 17) Three two-stage pump sets, 18) Chamber, 19) Condenser, 20) Condenser plates, 21) Hydraulically operated valve between chamber and condenser, 22) Venting system

The chamber and condenser are in the same vacuum chamber, separated by a wall in which the valve is incorporated, providing the shortest possible path for the water vapor. The condenser and the brine heat exchanger are cooled by LN_2. The condenser surface consist of plates, and its temperature can be controlled between –110 and –60 °C. The shelves can be controlled by the circulated brine between –70 °C and +50 °C. The trays with vials can be loaded and unloaded from a trolley. The bottoms of the trays are removed before freezing. The shelves can be pressed together in one block and the trays are loaded onto the shelves by pushing one shelf after another in front of the trolley. Besides the shelf design (Section Uniformity of Temperatures, Pressures, and Product) and water-vapor transport (Section Water–Vapor Flow) chemical engineering is especially involved in the venting and the water–drainage systems, condenser design, and the optimum location of the vacuum pump connection. The gas-inlet filters (0.2 µm pore width) must be sterilized together with the plant. The integrity of the filters after sterilization must be proved and documented. The water intrusion test (WIT) is summarized: The known volume of the filter housing is flooded with sterile water at a defined pressure, and the change in pressure over time is measured. From this information the rate of water movement is determined. This is compared with the known data of an integer filter. After the test the filter and its housing have to be dried to remove all traces of water. Figure 22 shows the arrangement for the test. To completely drain the water after cleaning and sterilization, the chamber and condenser bottom should be inclined towards the drain, the water must flow freely from the vessels and through the piping, the valves have to be free of dead ends (diaphragm valves are preferred), and drain ports should have steam traps to prevent re-contamination from the drain lines. The condenser design is easy to formulate but becomes more and more critical to engineer with decreasing pressure: All water molecules must impinge on the condenser surface at least once, the partial pressure of the noncondensable gases must be small compared with the water vapor pressure at the entrance to the condenser, and the water vapor pressure at the entrance to the pumping system should be equal to the equilibrium pressure at the condenser temperature. The engineering aspects require effective cleaning and sterilization, a small temperature drop from the entrance to the exit of the refrigerant in the condenser coils or plates, and an acceptable temperature gradient from the ice surface to the metal surface of the condenser.

Figure 22. Filter integrity test by the water–intrusion method (WIT). (Fig. 2.46 from [7].)

1) Primary filter, 0.22 µm cartridge; 2) Secondary filter, 0.22 µm cartridge, backup filter can be sterilized independently from filter 1; 3) Test liquid reservoir (water for injection, WFI); 4) Inlet valve for WFI; 5) Pure steam inlet valves; 6) Inlet valve for filtered air (5 bar absolute); 7) Inlet valve for venting gas (1060 mbar); 8) Drain line with valves; 9) Connection for water ring pump; 10) Connection to condenser; 11) Connection to chamber; 12) Sanitary valves (diaphragm valves with no dead ends); 13) Temperature sensors

Figure 23 shows a schematic of a water vapor condenser. D is the mushroom-shaped formed valve plate, which directs the water vapor to the condenser surface. The condenser coils have a similar surface to the shelves for easy cleaning, and the coils are arranged, e.g., in three or four rows behind each other, as shown in Figure 24. The opening in one row is closed by the tube in the next row or in the next two rows. The distance between the two tubes is for the ice to build up, the next or the next two tubes in the next row or the two next rows have a similar distant from each other and from the other row(s) to provide space for the condensed ice. In this way the water molecules not condensed on the first row of tubes can condense on the tubes of the second or third row. To take care of the decreasing amount of vapor the condensers can have a cone for displacement of the vapor on the valve drive (Fig. 23) or a conical housing. The permanent gases are pumped off below the condenser coils as shown in Figure 23 and 25. If the gas is pumped off at a higher point, the condenser below this point will be gradually filled with gas (air is heavier than water vapor). This gas reduces the efficiency of condensation and finally stops it. If the gas pressure in the chamber or the condenser is not small compared with the vapor pressure, then instead of glassy ice, a porous snowlike ice is formed (Fig. 26), which can have ten times lower thermal conductivity. If the partial pressure of the permanent gases is too high it influences four steps of the process: It reduces water vapor transport from the chamber to the condenser (prolonging the MD time up to collapse of the product), it reduces the efficiency of vapor condensation even to the point of stopping vapor transport, decreases the thermal conductivity of the ice by a factor of up to 10, prolongs the SD time, and limits the possible minimum RM.

Figure 23. Schematic of a water–vapor condenser for a freeze drying plant (Fig. 2.18.1 from [7]). A) free diameter of the connection to the chamber, B) cylindrical opening by the movement of D, C) opening between condenser wall and valve plate, D) valve plate, hydraulic valve drive, E) condensation surface of the refrigerated coils, F) in- and outlet of the refrigerant, G) tube connection to the vacuum pump, H) water drain during defrosting of the condenser; p_{ch} and p_{co}: pressure in the chamber and in the condenser respectively.

Figure 24. Condenser with four rows of condenser coils. (Fig. 2.64.2 from [7]).

Figure 25. Schematic of a condenser design. (Fig. 1.90.3 from [7].) Condenser wall, 2) Condenser coil, 3) Suction tube of vacuum pump, 4) Water drain, 5) Connection to drying chamber, 6) Valve with seal in closed position, 7) Valve in open position.

This condenser design is not an optimum for three reasons: The open valve (7) restricts the vapor flow in the connection 5, water molecules can reach (4) without impinging (2), the vacuum connection 3 ends higher than the lowest condenser coil (2)

Figure 26. Coils in a condenser covered by ice, observed through a window during two freeze-drying processes. Left: smooth, solid surface. Right: porous, snowlike surface which typically occurs if the pressure of permanent gases during MD is too high (photographs by Otto Suwelack, 48727 Billerbeck, Germany).

The vacuum pumps have to be laid out for two criteria: Evacuation time of the plant to the operating pressure (recommended: 10 to 20 min) and capability to pump off the permanent gases during SD. Figure 27 shows the pumping speed of a three-stage combination: a Roots pump EH 500, a Roots pump EH 250, and a dry vacuum pump GV 80. The dry vacuum pumps operate without oil as a sealing medium, which avoids possible backstreaming of oil vapor into the condenser or the chamber. This pump set will evacuate a 4 m^3 plant (empty chamber and condenser) in ca. 16 min to ca. 10^{-3} mbar and has a capacity of ca. 300 m^3/h at 10^{-3} mbar. The gas desorption of the product and the plant is difficult to estimate at a pressure of 10^{-3} mbar, but to give an idea of the order of magnitude the following can be considered: The gas desorption of a product will be much smaller than the water desorption, which at the end of SD could be 0.1 %/h; at a load of 2000 g solids in the ca. 2 m^3 chamber this corresponds to 2 g/h, and degassing may be 0.02 to 0.2 g/h. The gas desorption of metals after 10 h of degassing is on the order of 2×10^{-9} mbar L s^{-1} cm^{-1} (chapter 2.4.1 in [17]). If condenser and chamber have a metal surface of ca. 50 m^2, they would degas 3–4 mbar L/h. The degassing of the product is estimated to be 0.02 to 0.2 g/h, which corresponds to 25–2250 mbar L h^{-1}. The pumping capacity (Fig. 27) at 10^{-3} mbar is 350 m^3 h^{-1}. Conclusions: the degassing of the metal surfaces in a freeze-drying plant can be expected to be small compared with the gas desorption of the product. The pumping speed as shown in Fig. 27 is sufficient to evacuate the plant in a reasonable time and to pump off the gas from the product. If the required end pressure of permanent gases is 10^{-2} mbar (example: see Section Pressure During Secondary Drying) the Roots pump EH 250 can be omitted.

Figure 27. Pumping speed of a three-stage pump set: two dry roots blowers EH 500 plus EH 250, and one dry vacuum pump GV 80 with a high pumping speed from 0.001 to 10 mbar, end pressure ca. 10^{-4} mbar. (BOC Edwards GmbH, D-85551 Kirchheim/ München, Germany)

The automatic loading and unloading of production freeze-dryers becomes more and more the technique of choice; it is described in Section Process Automation.

5.2. Regulatory Requirements for Pharmaceutical Plants

The FDA defines (1993) the process validation as “establishing documented evidence which provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes”.

The Guide to Inspections of Lyophilization of Parenterals, published by the FDA (July 1993) contains among others the chapters Lyophilization Cycle and Controls, Cycle Validation, and Lyophilizer Sterilization/Design.

In the European Union, the directive 91/356 EEC provides the principles and guidelines of Good Manufacturing Practice (GMP).

The following are a few of the most important European and U.S. guidelines [18]:

- GAMP: Good Automation Manufacturing Practice [19]
- EC-GMP Guidelines and Annex 15-PIC/S PI 006-1 and FDA Regulations (PIC/S = Pharmaceutical Inspection Convention) [20])
- User Requirements DIN 69905
- ISPE Commissioning and Qualification [21]

- The Parenteral Society — Specification and Validation of Freeze-dryers No. 9
- GXP: Good Practices for Computerized Systems in regulated GXP Environments [18]
- FDA: 21 CFR Part 211, § 211.68 (a, b)
- FDA: 21 CFE Part 11, “Electronic Signature, Electronic Records” [22]
- ISO: 100 11 Guidelines for Auditing Quality Systems [18]

The FDA defines a validation plan as a guideline of principles of general process validation. It should include the following:

1 Qualification and Validation Principles: This describes the principles of qualification and validation. It is a GMP requirement that manufacturers identify the validation work needed to prove control of the critical aspects of their particular operations.

2 Planning for Validation: All validation activities should be planned in a validation master plan (VMP). The plan should contain at least the following: validation policy, organizational structure of validation activities, summary of facility systems, equipment and processes to be validated, documentation format, planning and scheduling, change control, and reference to existing documents.

3 Documentation: A written protocol should be established that specifies how qualification and documentation will be conducted. The protocol should specify critical steps and acceptance criteria.
After completion of a satisfactory qualification, a formal release for the next step in qualification and validation should be made as a written authorization.

4a Design Qualification (DQ): The first element of a validation system or equipment should be the design qualification. The compliance of the design with GMP should be demonstrated and documented.

4b Installation Qualification (IQ): IQ should be performed on new or modified systems and equipment. IQ should include, but not be limited to, the following:
- Installation of the equipment, piping, services, and instrumentation, checked to current engineering drawing and specifications
- Collection of supplier operating and working instructions and maintenance requirements
- Calibration requirements
- Verification of materials of construction

4c Operational Qualification (OQ): OQ should follow IQ. OQ should include, but not be limited to the following:
- Tests that have been developed from knowledge of processes, systems, and equipment
- Tests to include a condition or a set of conditions and encompassing upper and lower operation limits, sometimes referred to as “worst-case” conditions
  The completion of a successful OQ should allow finalization of calibration, operating, cleaning and sterilization procedures, operator training, and preventative maintenance requirements. It should permit a formal “release” of the systems and equipment.

4d Performance Qualification (PQ): PQ should follow successful completion of IQ and OQ. PQ should include, but not be limited to, the following:
- Tests using production materials, qualified substitutes, or simulated products that have been developed from knowledge of the process and the systems or equipment
- Test to include a condition or set of conditions and encompassing upper and lower operating limits
- Although PQ is described as a separate activity, it may in some cases be appropriate to perform it in conjunction with OQ

5 Process Validation: This is the documented evidence that the process, operating within established parameters, can perform effectively and reproducibly produce a medical product which meets predetermined specifications and quality attributes.

6 Cleaning Validation: The cleaning process must be defined and the parameters described in writing. The limits and test procedures must be described.

7 Sterilization Validation: The sterilization process must be defined and the parameters described in writing. The limits and test procedures must be described.

8 Change Control: Written procedures should be in place to describe the actions to be taken if a change is proposed to a starting material, product component, process equipment, process environment, method of production or testing, or any other change that may affect product quality or reproducibility of the process.

9 Re-validation: This is a repeat of process validation to provide an ensurance that changes in the process/equipment introduced in accordance with change control procedures do not adversely affect process characteristics and product quality.

10 Risk Analysis: This is a method to access and characterize the critical parameters in the functionality of an equipment or a process.

11 Worst-Case Scenario: This is a condition or set of conditions encompassing maximum and minimum processing limits and circumstances within standard operating procedures which pose the greatest chance of a product or process failure when compared to ideal conditions.

Figure 28 shows the different steps in a qualification model following Good Automation Manufacturing Practice (GAMP).

Figure 28. Qualification model following GAMP guideline. (Fig. 6.3 from [7].)

The content of this section is not at all a complete description of the regulatory requirement for a freeze-drying plant to produce pharmaceutical products; it provides some examples of what must be considered in a long and complex process.

5.3. Food Plants

Food plants can be of the chamber or continuous type. Theoretically, food could be freeze-dried in chambers like pharmaceuticals, but the main problem is the freezing of products with different shapes and the handling of large amount of products; the cleaning requirements remain, but sterilization is not necessary. The freezing of food uses a variety of methods, of which the three main ones are: (1) freezing in a flow of cold gas, (2) freezing of droplets in a cold liquid and (3) prefreezing of a foam with final freezing in cold air.

Method 1 uses cold gas at a temperature from, e.g., –40 °C to the temperature of LN_2. If sticking together of, e.g., peas or leaves must be avoided, the surface of the product is quickly frozen with LN_2 in a CRUSToFREEZE plant (capacity 1500–5.000kg/h; Fig. 29) and finally frozen on a conveyor belt. In method 2 droplets of the liquid product are frozen in LN_2, as schematically shown in Figure 30. Coffee and tea extracts are foamed in method 3 by N_2 or CO_2 during cooling and partial freezing (e.g. to –5 °C) in a type of ice-cream machine. This foam must have a particular density, with the inclusion of certain amount of small ice crystals. The foam is cooled on a conveyor belt at –40 °C or below, as this product must pass a grinding and sieving system to achieve a desired grain size and density. The frozen product is dried mostly in two types of trays (Fig. 31). The ice sublimation rate of five types of trays is given in Figure 32. The tray types 3 to 5 in Figure 32 are more expensive than type 1, but the increase in the ice sublimation rate is 300 to 400 %. Food is mostly freeze-dried in heating systems installed in cylindrical chambers (Fig. 33) with outside (A) or built in condensers (B). The cylindrical chambers can be loaded and unloaded with product in trays: (A) by a carrier and transport device in which the trays (types 2 to 5 in Fig. 32) are loaded or (B) by an elevator which adjusts to the different heights between the heating plates and pushes the trays (type 1 in Fig. 32) on guide rails into and out of the chamber. In both cases, two to four of these tunnel sections can be put together, and vacuum locks be added on both ends. In design A a complete carrier with trays is moved into the lock, which is evacuated, and then the carrier is moved into the drying position, where the trays are lowered onto the heated shelves. In design B the trays remain on their guide rails and are pushed through the drying zone on one level, then an elevator brings them to the next level. The trays are brought individually through a lock into the chamber and through another lock back to the atmosphere. In the type-A plant up to 5000 t of freeze-dried coffee granules can be produced per year, and in the type-B plant up to 3000 t/a. Continuous freeze-drying plants have been built in which granules are transported on vibrating heated shelves. This method increases the water evaporation rate by a factor of ten or more. The limitation is the amount of product carried away by the dense water vapor flow or the need to filter the vapor flow with filters having a very large surface area to reduce the pressure drop through the filters.

Figure 29. Schematic of the IQF freezing process CRUSToFREEZE (AGA AB, Frigoscandia Equipment AB, S-25109 Helsingborg, Sweden).

Figure 30. Schematic of a Cryogen Rapid Pelletizer. 1) Dropper unit, 2) Pelletizing channel, 3) Insulation, 4) Ventilator, 5) Product, 6) Conveyor belt, 7) Return channel for LN_2, 8) LN_2 pump, 9) Transport containers. (Messer Griesheim GmbH, D-47805 Krefeld, Germany.)

Figure 31. Types of tray for freeze drying cubes or granules of food.

Tray a: e.g., 400×500 mm, 30 mm height; tray b: e.g., 500×160 mm, 50 mm height.

Figure 32. Ice sublimation rate (kg m^{-2} h^{-1}) for five different types of trays.

1) Flat tray as in Fig. 31a, with 20 mm filling height. 2) Flat tray with one rib of 20 mm height. 3) Ribbed tray, rib distance ca. 7 mm. 4) Ribbed tray with a V-shaped sieve between the ribs. 5) Ribbed tray for cubes or granules of food, designed by Otto Suwelack, D-48723 Billerbeck.

All tests were carried out with the same granulate. Hatched columns: heating plates or shelves were heated in ca. 30 min to 100 °C, and when the tray bottom reached +40 °C, the temperature was reduced in such a way that +40 °C was kept constant. White columns: heating plate or shelves were heated to +140 °C in ca. 2 h and the temperature reduced after +40 °C was reached as above (measurements by Otto Suwelack, D-48723 Billerbeck, Germany).

1) Drying tunnel. In A: 2) Valve before the condenser, 3) Lifting and transport device, 4) Trays in transport position, 5) Trays on the shelves during drying, 6) Heated shelves. In B: 7) Radiation plates, 8) Trays, 9) Guide rails for the tray transport, 10) Separating plate between tunnel and condenser, 11) Condenser, 12) Vacuum connection.

5.4. Process Automation

5.4.1. *Prerequisites for Process and Plant Automation*

For the automation of freeze-drying processes and plants the qualities of the product, the qualities of the plants, and the developed process data have to be known, with emphasis on the acceptable tolerance of each datum and their cross dependence, e.g. p_c = 0.1±0.01 mbar may be tolerable if T_{sh} = 0±0.1 °C; If this tolerance cannot be achieved, and only 0±0.3 °C is possible, but at 0.3 °C p_c = 0.11 mbar is too high, than p_c should be specified as 0.09±0.01mbar. The plant data should include a failure analysis to highlight possible soft spots and eliminate them before automatization. The second requirement is to specify the measuring method for the data, e.g., all pressure gauges are of the capacitive type with temperature compensation for the range –40 to 60 °C, the reproducibility over a period of three months is better than ±0.003 mbar. To measure a temperature in the product during MD temperature sensors can not be used (the plant is automatically loaded and unloaded). During product development, at the latest in the pilot-plant phase, T_{ice} must be determined by BTM (see Section Barometric Temperature Measurement (BTM)), perhaps in parallel to temperature sensors in the product. Thermal conductivity gauges are too inaccurate for freeze-drying data and in addition depend on the type of gas, which varies in freeze-drying from 90 % or more water vapor to more than 90 % permanent gases desorbed from the product and the inner plant surfaces (see Section For Pharmaceutical Products). If different pressure gauges are used or T_{ice} is not measured, the whole product development and the pilot cycle may have to be repeated to gain documented data for an automation qualification and validation. These principles apply both for pharmaceuticals and food.

5.4.2. *Control of the Process and the Plant by Thermodynamic Data Measured During the Process: Thermodynamic Lyophilization Control*

The freezing of food is mostly automated due to the large volumes to be handled (see Section Food Plants). The loading and unloading of pharmaceutical freeze-drying plants is becoming more and more automated for two reasons: the handling of 10 000 to 100 000 vials is time consuming and burdened with the chances of several errors; the people handling the vials must sometimes be protected from the product, and each operator in the loading area increases the chances of product contamination. Two concepts of automatic loading and unloading are mostly used to day:

1. Automated guided vehicle (AGV): The vials are transported between the filling machine and the drying chamber or between the drying chamber and the capping machine by means of an AGV (Fig. 34).
2. Push and pull system: The vials are taken from the filling machine directly to the front of the Freeze-dryer by means of conveyors and pushed onto a shelf in the drying chamber (Fig. 35). Unloading of the drying chamber is effected over a pulling system: the vials are pulled out of the drying chamber and placed on a conveyor belt which transports them to the capping machine.

Figure 34. Sterile wall with two freeze drying plants (10 m^2 shelf area each), one loading storage (front) with ten divided shelves and one unloading storage (behind transfer cart). The loading and the unloading storage are served by the battery-driven transfer cart (in the background). (Novartis, Stein/Basel, Switzerland.)

Figure 35. Automatic loading and unloading system in front of the freeze drying plant (Steris GmbH, D-50354 Hürth, Germany.)

To separate product and operator completely the filling, transport and loading system can be enclosed in isolators as shown in Figure 36.

Figure 36. Automatic loading and unloading system completely enclosed in insulators. (Steris GmbH, D-50354 Hürth, Germany).

Cleaning and sterilization of pharmaceutical plants is becoming more and more automated for two reasons: human errors have to be reduced to a minimum and both processes have to be documented, qualified, and validated. Cleaning in place (CIP) has to take the four T principles into account [32]:

1. Temperature: Thermal effect; an increase in temperature of 1 °C increases the cleaning efficiency by 5 % (above 30 °C).
2. Turbulence: Mechanical effect; turbulence, as defined by the Reynolds number *Re* is basically a function of flow velocity and viscosity. For successful CIP the flow velocity in the pipes should be a minimum of 2 m/s (or *Re* > 8000); flat spray jets are used for cleaning the chamber, the pressure at the outlet should be in the range of 6 bar.
3. Time: Effect of the cleaning time.
4. Titration: Chemical effect; this is the influence of the chemicals in the detergents, cleaning agents or acids used. The concentration of these chemicals depends on the degree of equipment contamination.

A typical cleaning process consists of the following phases:

- Preliminary rinse with demineralized water (DE) or water for injection (WFI)
- Cleaning process with a cleaning solution or a detergent
- Final rinse, preferably with WFI

The process must be carried out in such a way that it can be validated. The following parameters are documented: water temperature, time, pressure, conductivity in the drain. CIP of Freeze-dryers requires extensive planning:

- Computer-controlled cleaning sequences with interlocks prevent unauthorized route-switching due to operator errors
- CIP processes can be sufficiently qualified and therefore fulfil CGMP requirements for validation
- The user develops a validation plan giving the highest and lowest limits for the verification of successful cleaning
- Verification of the correlation between the amount of product residuals in the last rinse water
- Optimization of the CIP process parameters until the desired level of cleanliness is reached

Steam sterilization is mostly used for freeze-driers. Only pure steam should be used; filtered plant steam has too high a content of permanent gases (regulation BS 3970). The recommendations of Section For Pharmaceutical Products should be applied for the plant design. The main design criteria are summarized:

- Free flow of the condensate from the vessels.
- Avoidance or minimation of “dead-ended” piping. The ratio of the pipe diameter to pipe length should be between 2 and a maximum of 6. (l/d = 2 to 6). Piping that comes into contact with operating media must also be sterilized. Such piping must be laid out with an inclination toward the chamber or condenser. Valves free of dead ends (sanitary valves) should be used exclusively. Diaphragm valves are recommended as the most appropriate valves.
- It must be possible to sterilize gauge heads. Particular care must be taken in choosing temperature-resistant gauges. A drifting of calibrated values at the high sterilization temperatures must be precluded.
- A certified sealing material which is FDA-compliant (21CFR 177.2600 and 21CFR 178.3570) should be used; e.g. PTFE or silicone.
- The temperature measuring points should be the coldest points in the system.
- Safety valves should be chosen which exclude any type of contamination of the vessels or piping when opened; in these valves the valve seat returns to the closed position after pressure has been released.
- If the door is equipped with a seal that provides tightness both in the vacuum and overpressure ranges, the door locking system must ensure that there is no gap between the door and the door flange at the lower areas of the door. Condensate can collect at the lower area of the door and chamber flange, and hence the sterilization temperature cannot be reached.

Steam sterilization can be replaced by the VHP (vaporized hydrogen peroxide) process, which works at ambient temperature and without pressure. Sterilization by VHP requires certain conditions which result from the nature of the H_2O_2 vapor:

- The plant must be dry, otherwise the H_2O_2 will dissolve in the water.
- The installation must be evacuated to ca. 1 mbar to ensure that the vapor reaches all parts and corners of the plant. H_2O_2 can still be applied at +5 °C, but at higher temperatures, e.g., +25 °C, the time to effect sterilization is shorter. Table 4 shows a typical set of *D* values (time in which the number of bacteria is reduced by a factor of ten) for *Bacillus stearothermophilus* for different surface temperatures and the necessary concentrations of H_2O_2.

Table 4. Typical *D* values (exposure time in which the number of bacteria is reduced by one order of

magnitude) for *Bacillus stearothermophilus* for different exposure times and the necessary H_2O_2 concentrations. (from [23])

Temperature of surface to be sterilized (°C)	Approx. H_2O_2 concentration (mg/L)	Typical *D* value (min)
4	0.3–0.5	8–12
25	1–2	1–2
37	3–4	0.5–1
55	10–12	0.02

The following technical prerequisites must be fulfilled:

Not all materials are resistant to H_2O_2. Stainless steel, aluminum, silicone, Viton, and Teflon are resistant; polyurethane, Plexiglas, and EPDM are not resistant in all compositions; and Nylon is not resistant. Pumps must be layed out to pump water which may be in the plant, but also to be resistant against H_2O_2. In smaller plants it is possible to use a catalyst to decompose the H_2O_2 in front of the oil-filled vacuum pump. In larger plants it is recommended to use a liquid-ring pump combined with an air injector for drying plant and venting the H_2O_2.

The sterilization process consists of three phases:

1. The installation is evacuated for drying to 1 mbar, or to at least below 10 mbar. For the documentation of the process the leak rate of the plant must be measured to prove that no outside air, perhaps contaminated, can enter the plant during phase 3.
2. For the sterilization phase a certain amount of H_2O_2 is injected into the plant and pumped off after some time. This procedure is performed once or may be repeated several times.
3. Removal of the H_2O_2: The vapor is pumped off by the vacuum pumps, the plant vented with sterile air up to 500 mbar, evacuated again, and so on. At the end of this procedure the residual H_2O_2 concentration is checked, e.g., by the Dräger H_2O_2 test tube [23], which indicates H_2O_2 concentrations down to 0.1 ppm.

The freezing of pharmaceutical products in vials by LN_2 can be documented by the temperature of the bath and the time involved. To document freezing on the shelves of the plant the inlet and outlet temperature of the brine in the shelves during freezing can be recorded, as in Figure 37, which permits the following conclusions from these runs:

– In this installation and with this load the beginning and the end of crystallization can be followed. At 20 min ca. 8 %, at 50 min ca. 60 %, and at 70 min ca. 90 % of the total energy has been removed from the product. The period 20 to 70 min is called here the main freezing time.

Figure 37. Thermodynamic data during freezing. All four curves are the average of two runs.

1) difference between inlet (T_i) and outlet (T_o) temperatures of the shelves of the plant with empty vials. 2) Same temperature difference during cooling with filled vials. The standard deviations between these 2 runs are given as figures on curves 1 and 2. 3) Energy used for cooling and freezing the product in percent of the total energy used. 4) Temperature in the product measured by sensors (2 sensors in 2 vials during each run). The curve is the average of these four temperatures, the numbers are the standard deviations of these 4 measurements. (Fig. 1 from [5].)

– The degree of subcooling was not uniform in all vials, as can be seen from the steps in plot 2. This is confirmed by the large standard deviations of the four sensors (plot 5): In the beginning between 30 and 60 min sd goes from 1.5 to 4.5 °C, then back to 0.5 °C, and in the end is 0.14 °C.

The optimum freezing time can be estimated by Equation (1) and compared with data as gained similar to Figure 37.

MD is controlled by T_{sh} and mainly by p_c (see Section Barometric Temperature Measurement (BTM)), as shown in Figure 38. T_{ice} is the temperature at which the heat input and the energy consumption by sublimation is in equilibrium. This temperature depends also on T_{sh}, the number of vials, the product structure and height, and the water–vapor flow density in the plant. (see Figs. 5-7). The plot in Figure 38 is only valuable if all these conditions are the same. T_{ice} follows a change of pressure in seconds, while a change in T_{sh} may take 30 min or more. For the control of T_{ice} the pressure is the most effective instrument. The optimum time of MD can be estimated by Equation (2). The quantitative change from MD to SD is described in Section Transition from Main to Secondary Drying (SD). The change can be automated by combining the steps of the change with decreases in T_{ice} (see Section Transition from Main to Secondary Drying (SD)), e.g., maximum $T_{ice/n}$ –1 °C, change T_{sh} from 0 °C to 30 °C; maximum $T_{ice/n}$ –2 °C, terminate pressure control p_c; limit the time span for the pressure to reach, e.g., 5×10^{-2} mbar to 15 min.

Figure 38. T_{ice} as a function of p_c. The shown plot is only valid under certain conditions.1) T_{ice} as a function of p_c, 2) saturation vapor pressure of ice. (Fig. 2.88 from [7])

SD is governed by three factors: the rate at which $T_{sh,SD}$ is reached, $T_{sh,SD}$ itself, and the pressure at which the desorption takes place. The course of SD can not be calculated. The optimum time in a plant is given (1) by the time for $T_{sh,SD}$ to reach its required level, e.g.. 30 °C at 2 °C/min, (2) the thermal conductivity of the product (the time for T_{pr} to reach, e.g., 28 °C is mostly the largest component of t_{SD}), (3) the water–vapor partial pressure must be small compared with the pressure given by the respective isotherm (example in Fig. 39), and the permanent-gas pressure must be small compared with the water vapor pressure. Automation during SD involves the repeated measurement of DR (e.g., every 15 min), the calculation of dW by the integration of DR over time, and automatic termination of the drying when the desired dW, e.g., 0.2 %, is reached. The dW data calculated from DR may not show the same figures as data determined by other methods, e.g., Karl Fischer method or thermogravimetry. Water in the dried product can be bound in many different forms, e.g., as surface water, as water bound more or less strongly to the dry substance, or as water of crystallization. Therefore, each method can lead to different results for different substances (for details, see [[7], sections 1.3.1 and 2.6.2.3]).

Figure 39. Desorption isotherms of the residual moisture content (wt %) as a function of water–vapor pressure. 1) 20 °C, 2) 40 °C, 3) 60 °C.

Thermodynamic lyophilization control permits, without temperature sensors in the product, automatically documented freezing, controlled and documented main drying, documented secondary drying, and termination of the total process at a required residual moisture content.

5.4.3. *Transfer of Pilot Plant Data to Production*

The transfer of pilot plant data to production often seems to be difficult, especially when in the pilot plant, e.g., 500 vials are loaded and the production plant handles, e.g., 50 000 vials. Five main reasons or a combination thereof impede the transfer:

1. The heat-transfer coefficients from the brine to the shelf surface are not comparable.
2. The water–vapor flow resistance from the chamber to the condenser surface as a function of pressure is different.
3. The influences of the wall and door temperatures on the product are not similar.
4. The condenser design and therefore its efficiency as a function of the operating pressure is not the same.
5. The pressure of the permanent gases during MD and SD is different.

For the following consideration it is assumed that methods and instruments of temperature and pressure measurements are identical, vials and the product are the same, and, very often important, the history of the product before the start of freezing and before the start of drying is the same.

One method to identify heat-transfer coefficients is described in Section Uniformity of Temperatures, Pressures, and Product. With shelf areas 100 times larger in production than in the pilot plant it is possible and even likely that the brine flow and the mass distribution of the steel in the shelves are not identical. One has to measure how important the difference is for the transfer of the process. During freezing the largest energy transport is required: During cooling and freezing one can expect ca. 400 kJ/kg of water, and during sublimation ca. 2800 kJ/kg. Cooling and freezing may take 0.5 to 1 h, the sublimation of the same product thickness takes 10 to 20 h; under these condition 800 kJ kg^{-1} h^{-1} during freezing and 280 kJ kg^{-1} h^{-1} during MD have to transported. It is therefore sufficient to compare the average temperature as a function of time in both plants on one shelf during freezing. Both shelves have to be loaded with the maximum number of identical vials filled with, e.g., 12 mm of water. The comparison of the average temperature is performed by a sufficient number of temperature sensors, e.g., 5 to 10 in the pilot and 20 in the production plant. The average difference between the plots of the two plants should not exceed 15 %, and the variation on the shelf in each plant should also not exceed 15 % from the average. If there are areas on the shelf with a deviation of more than 15 % the reasons for it have to be analyzed. 15 % is on the high side, 10 % should be more likely; therefore 15 % is mostly the starting point for critical differences.

Water-vapor flow is discussed in Section Water–Vapor Flow, including an example. It may be repeated here: With decreasing pressure (below 0.1 mbar) the possibility increases that the production plant does not have an opening between chamber and condenser comparable to that of the pilot plant. Before transferring a process to production, the water vapor flow density in both plants should be measured at two or three different pressures. These measurements in the production plant will not take longer than a few hours for the sublimation; the time for loading and unloading and weighing must be added. All can be done under sterile conditions if required.

The influence of door and wall temperatures on the uniformity of the residual moisture content is shown in Section Uniformity of Temperatures, Pressures, and Product. The guidelines for shielding have to be applied specially in large plants, since the mass of steel around the product will follow the shelf temperature more slowly. Even if a system is installed to cool the chamber more quickly after sterilization, it remains ineffective in adjusting the door and wall temperatures in time to the shelf temperature. There is no general rule for what type of shielding will be sufficient; it depends mainly on two factors: the larger the temperature difference between shelf and wall during freezing, main drying, and secondary drying, the more careful is the shielding required; the higher the operating pressure (e.g. < 0.1 mbar) the more the convection and the conductivity of the gas will contribute to heat transfer between walls and product; at pressures below 0.01mbar one may expect overwhelmingly radiation, which is easier to control than a mixture of all three contributions. Only during freezing on the shelves under atmospheric pressure can the influence of the three methods of energy transfer to the product not be avoided, except by using temperature-controlled shields.

The positions of pressure measurements in the chamber of the pilot and production plants must be evaluated. The pressure should be measured at a point of very low vapor velocity; at a point of high velocity the difference between static and dynamic pressure could theoretically reach almost a factor of two, but a difference of 20 % between pilot and production plant would lead, e.g., in the range of T_{ice} –30 °C to a difference of ca. 2 °C. This error would be five times larger than acceptable. High vapor speed will be near the connection between chamber and condenser. In the condenser the pressure should be measured in a part where the water vapor is in equilibrium with the condenser surface, where only this vapor pressure and the pressure of the remaining permanent gases is measured.

Differences in pressures between pilot and production plant during MD to obtain the same T_{ice} mostly indicate different flow resistance behavior of the two plants, which must be accepted unless the possible load of the production plant becomes too low. The other reason can be different leakage rates of the plants. Leak rates of both plants should be measured in such a case. (A leakage rate large enough to change T_{ice} measurably is unacceptable for DR measurements). A different pressure during SD at the same condenser temperature, leakage rate excluded, indicates a different pumping characteristic of the pump set. Some times the pumping speed at low pressures (e.g., below 5×10^{-2} mbar) in production plants is relatively lower than in a pilot plant. This can delay SD or make a small RM impossible.

6. Some Examples of Freeze-drying Processes

6.1. For Pharmaceuticals

Three processes for pharmaceutical products are described to demonstrate the reproducibility of a process the possibility of shortening the process time, and optimization of a process by the selection of excipients.

6.1.1. *Process Reproducibility*

In Figure 40 10 % sucrose solution is taken as a model substance to show the reproducibility of a total process. In the three runs the history of the product and the process data are kept as identical as technically possible. The standard deviation of T_{ice} in the three runs is 0.11 °C, and this indicates a high degree of uniform structure in the frozen product; T_{sh}, T_{co}, and p also show that the data were closely controlled. The result is shown in Figure 41 by the behavior of the three product runs during SD. The dotted lines represent the dW data calculated from DR measurements; the crosses, circles, and triangles each represent one measurement by thermogravimetry at 55 °C (see Section Residual Moisture Content). For these measurements vials were closed at the indicated time, and the residual moisture was determined after the end of drying. For the reproducibility of freezing and drying in this model of a pharmaceutical product one can conclude the following:

In spite of close freezing and drying control the three runs show small but measurable differences.

During main drying these differences are not measurable.

The time of change from MD to SD varies by less than ±0.5 h, depending on the decisions how to change (see Section Transition from Main to Secondary Drying (SD)), a variation of ±0.5 h can be expected and may be shortened by reducing the time between two measurements, e.g., 8 min instead of 15 min.

RG data (Fig. 41) before and during the change from MD to SD vary by up to a factor of eight. Thereafter the variation is more and more reduced and in the end (0.3 %) identical with dW.

The change from sublimation to desorption is not uniform in all vials; only when the residual moisture is on the order of 1 % of the solids does the whole charge become more uniform in this case.

The differences in the three dW plots result partially from point 3 above, but the differences in dW data show the necessity of SD documentation if small dW and/or small tolerances of dW are required.

If only 1 to 2 % dW is required ca. ±0.5 % from average can be expected.

Figure 40. Process data of three freeze drying runs, vials filled with a 10 % sucrose solution, filling height 10 mm.

1) Shelf temperature T_{sh}, 2) Product temperature by sensors, 3) Chamber pressure, 4) T_{ice} by BTM, 5) Condenser temperature. Double lines of the same data indicate the maximum and minimum values measured. T_{ice} for the three runs

are: –34.99, –35.02, and –34.81, average T_{ice} of the three runs is –34.94 °C, sd 0.11 °C. Freezing rates: run 1: 0.7 °C/min, run 2: 0.65 °C/min, run 3: 0.75 °C/min. (Fig. 4 from [25]).

Figure 41. dW data calculated from DR measurement: runs 1, 2, and 3 dotted lines, compared with data from gravimetric measurements (RG): run 1 ×, run 2 •, run 3 ▲. For RG measurements 10 vials were closed at the shown time and measured after the end of SD. (Fig. 5 from [25]).

6.1.2. *Shorter Drying Cycle*

Figure 42 and 43 show the freeze-drying course of a Factor VIII solution. The product has a filling height of 27 mm and must be frozen in LN_2 at the rate of freezing that should be > 15 °C/min, otherwise the dry product becomes a powder if shaken. The ER measurement shown in Figure 44 requires $T_{ice} \approx$ –55 °C if frozen at 15 °C/min. If the product is thermally treated at –45 °C for ca. 9 h (the frozen product rests on the shelves at – 45 °C for 9 h and is then dried), the cryomicrographs (Fig. 45) show that the product can now be dried at $T_{ice} \approx$ –40 °C (the unfrozen water due to the high freezing rate has now being crystallized). From Figures 42 and 43 one can draw the following conclusions for the process:

1. T_{sh} can be raised in one step from –42 °C to e.g. –6 °C.
2. The pressure difference between the sublimation surface (–40 °C ≈ 0.128 mbar) and the chamber pressure (0.048 mbar) is almost a factor of three, which is unnecessarily large. In choosing a factor of two (which is conservative), p_c could be raised to 0.06 mbar, reducing the transported water-vapor volume by 25 % . Since the heat-transfer coefficient in this pressure range depends very little on the pressure, the higher pressure is only advantageous if the vapor transport from the chamber to the condenser is the bottleneck of the process (see Section Water–Vapor Flow). At a higher pressure, one could load more vials into the chamber. In the experiment described, vapor transport is not the bottleneck; therefore, one cannot expect a reduction in drying time as a result of higher pressure.
3. Based upon the earlier increase of T_{sh} (Section Barometric Temperature Measurement (BTM)) and the higher p_c (resulting in a slightly higher T_{ice}) the temperature increase to +20 or +40 °C, respectively, could be done earlier, probably by a few hours.
4. The temperature in the product rises only slowly, even after the increase in T_{sh}, (in 10 h from –20 to 0 °C and in a further 10 h from 0 to 30 °C). The temperature rise could be accelerated: The shelf temperature is increased, e.g., to 50 °C until the product has reached +25 °C. At that time T_{sh} is reduced to +40 °C. This temperature increase takes ca. 16 h with a temperature difference T_{sh}–$T_p \approx$ 30 to 35 °C. The higher difference of ca. 40 to 45 °C should again save several hours.
5. The pressure control could be cut off at 66 instead of 72 h, shortening the drying time by an additional 3–6 h.
6. In total, 10–15 h can be saved, resulting in a drying cycle of 64–59 h instead of 72 h, which could mean the completion of a cycle in 3 rather than 4 d. On the other hand, it is not likely that the drying time under the given conditions (filling height 27 mm and T_{ice} = –40 °C) can be reduced to 40 h.

Figure 42. Freeze drying course of Factor VIII solution after freezing in LN_2.

Figure 43. Plot of the temperature at the sublimation front (T_{ice}) of the run shown in Fig. 42 (Fig. 10b from [27]).

Figure 44. Electrical resistance as a function of temperature of three Factor VIII solutions with different excipients (Fig. 5 from [27].)

Figure 45. Photographs taken with a cryomicroscope of Factor VIII solutions at four temperatures. At –40 °C the structure is still visible, but is coarser than at –44 °C. At –35 °C the structure has collapsed. (Fig. 6 from [27].)

6.1.3. *Selection of Exipients*

The excipients are chosen for their cryoprotection during freezing and their lyoprotection during drying and storage. The used excipients also determine the possible T_{ice} during main drying and the storage temperature. Table 5 shows the $T_{g'}$ and UFW data of some exipients. $T_{g'}$ of a combination of exipients and drugs can not be calculated from the data of the pure substance; each combination must be measured. Figure 44 demonstrates the influence of different exipients on the structure of the product with the same drug (Factor VIII). The three products should be freeze-dried at T_{ice} = –55 °C (1), –51 °C (2), and –35 °C (3). The consequences of these requirements are shown in Table 6 and listed here:

1. The production of product 1 with the data as in Table 6 is practically impossible: In a plant having a valve between chamber and condenser with a diameter of 800 mm only 500 vials with 30 mL could be dried in one charge.
2. This picture is not substantially changed if product 2 is studied.
3. In both cases the following can be concluded: at T_{ice} = –45 °C p_c could be ca. 0.03 mbar and the load could be ca. 5000 vials. At –45 °C it is possible that the mobility of the molecules is small enough (the product behaves like a solid in the mechanical sense) to maintain a certain structure during MD. It is difficult to predict the outcome by analytical measurements. Tests in a pilot plant must prove an acceptable quality of the dried product. One should be aware of the fact that 1 or 2 °C more or less can change the outcome of such a test. It is therefore recommended to start the first test at the lowest possible p_c with a calculated number of vials. If this test is not sufficiently satisfactory between –45 and –48 °C the chances of producing an acceptable product with today's technnology are small.
4. At these low pressures p_c and low T_{ice} the required condenser temperatures are not the limitations, nor are the permanent-gas pressures.
5. The energy input and the permeability of the dry gas are also not the limit, as can be calculated by Equation (2): With T_{tot} = 30 °C and a heat-transfer coefficient K_{tot} = 33 kJ m^{-2} h^{-1} °C the main drying time would be estimated as ca. 60 h. K_{tot} = 33 is not the maximum possible, but at these low pressures only vials with a flatter bottom or smaller vials with more chances of contact with the shelf could reduce t_{MD}. In the end this might not even be helpful, since the limitation by the water–vapor flow remains.
6. The selection or combination of excipients can make the freeze-drying of a product impossible, technically difficult, or as normal as for many other products.

Table 5. $T_{g'}$ and UFW of some exipients (data from [26])

Excipient	$T_{g'}$ (°C)	UFW (%)
Sucrose	–32 (–33.6*)	35.9
Maltose	–30	20
Lactose	–28 (–29.7*)	40.8
Trehalose	–30	16.7
Fructose	–42	49.0
Glucose	–43	29.1
Glycerol	–65	45.9
Sorbitol	–43	18.7
Dextran	– 9	
Albumin	–10	
Poly(vinyl pyrrolidone)	–19.5 (–21.1*)	
Poly(ethylene glycol)	–13	
Sodium citrate/citric acid	–40	
Na_2PO_4/KH_2PO_4 (1/1)	–80	

*Data from 1998.

Table 6. Estimated production data for products 1, 2, and 3 in Figure 44

	T_{ice} (°C)	$T_{sh,MD}$ [a] (°C)	p_c [b] (mbar)	$T_{co,MD}$ [c] (°C)	$T_{sh,SD}$ (°C)	$T_{co,SD}$ [d] (°C)	p_{SD,H_2O} [e] (mbar)	$p_{SD,pg}$ [f] (mbar)	Load[g] (vials)
1	–55	–25/–6	$7\ 10^{-3}$	< –68	35	<–77	$1\ 10^{-3}$	$< 3\ 10^{-4}$	500
2	–51	–20/–6	0.015	<–62	35	<–63	$7\ 10^{-3}$	$< 2\ 10^{-3}$	1500
3	–35	–6	0.048	<–53	35	<–60	$1\ 10^{-2}$	$<3\ 10^{-3}$	10 000

[a] $T_{co,MD}$ is chosen similar as in product 3 (Fig. 44), resulting in T_{tot} (Eq. 2) ≈30 °C. For products 1 and 2 the difference between –6 °C and –55/51 °C would result in a temperature gradient over the ice thickness of 27mm at the beginning of the drying, which softens or collapses the product near the bottom of the vial. On the other hand –25 °C/–20 °C can not remain during MD since the dry product can not exceed –25/–20 °C, at which temperature the end of sublimation and the beginning of desorption (or the change from one type of drying to the other) may take days or more in this case.

[b] p_c in accordance with the data of Figure 38.

[c] $T_{co,MD}$ = maximum condenser temperature during MD.

[d] $T_{co,SD}$ = maximum condenser temperature during SD.

[e] p_{SD,H_2O} = water–vapor partial pressure during SD.

[f] $p_{SD,pg}$=partial pressure of permanent gases during SD.

[g] Load: approximate number of vials filled with 30 mL of solution (5 % solids) in a production plant having a valve diameter between chamber and condenser of 800 mm; the main drying time is estimated as 60h. The water–vapor flow density is taken from Figure 13 with *l*/*d* = 1.6.

6.2. For Food

Examples for freeze-drying food include mushrooms, which is relatively straightforward, and the freeze-drying of coffee extract, which has many more steps and is typical for the compromises in food freeze-drying: economy versus quality. In Section Food Plants plants are described with an output of 3000–5000 t/a of dry granules. Assuming a concentration in the coffee extract of 38 % solids, between ca. 8000 and 13000 t of concentrate must be treated annually, or ca. 1.5 t of extract must be treated per hour. The quality of the freeze-dried product starts with the quality of the raw beans, the roasting, and the extraction. Freeze-drying can preserve the qualities; it does not improve them. The freezing of the extract is described briefly in Section Food Plants. The goal of these steps is to produce frozen slabs, which can be broken and milled to granules of a desired grain size distribution and bulk density. These processes involve chemical engineering at low temperatures. The frozen, broken slabs have to be milled to, e.g., granules between 0.3 and 2.5 mm. The resulting powder, e.g., smaller than 0.1mm, can not be used for drying as it will close the channels between the larger grains and hinder or block the flow of water vapor, and the product melts and sinters together in areas with too much powder. The milling and sieving process must be performed below –40 °C; otherwise, the grains become too warm and stick together; the actual temperature of the air in those cold rooms is close to –50 °C. Figure 46 shows a compact granulating and sieving installation. Such installations are completely automatic; transportation of the granulates is achieved by vibration, but they have to be cleaned and maintained by personnel. Ice sublimed from the milled and transported product grows over time at the coldest places. Freezing and granulation of the extract is, as with many other food and nonfood products, the decisive phase of freeze-drying; the quality of the product produced here can be preserved not improved (but deteriorated). For drying, the granules are filled into trays (Fig. 31), each containing ca. 3 kg of frozen granules. About 500 of these trays must be automatically transported, filled, emptied, and cleaned per hour. The ribbed trays often have built-in sieves or other elements to transport the water vapor from the grains to the chamber; as shown in Fig. 32, only with such elements can high sublimation rates (2.5–3 kg of ice $m^{-2}\ h^{-1}$) be achieved. The main drying time with such trays is 7–8 h. Figure 47 shows a schematic of a continuous freeze-drying plant designed for ribbed trays. Four carriers for trays are used in each tunnel section. After the end of drying, gate valve 7 to lock 10 is opened and all carriers are moved one position forward. During this time the gate valve 7 to the entrance lock is closed, the locked door opened, and one carrier is moved into the lock. This is evacuated and the carrier is moved into the first position inside the drying tunnel, and so on. During movement of the carrier the trays are lifted from the shelves and placed back on the shelves when the transport of the carrier is finished.

The shelves in each tunnel section can be operated at a different temperature, in the first tunnel section the shelves can be operated at two different temperatures, permitting a temperature profile of six steps, e.g., 20 °C to sublime ice, which is condensed on the carriers and trays; 80 °C in the second half of tunnel section 1, tunnel sections 2, 3 and 4 40 °C and 30 °C in tunnel section 5 to allow the product to cool down to max. <40 °C before unloading. The condensers are not equally distributed but concentrated at the first two tunnels. Of the four condensers at the first two tunnels three are in operation and one is being defrosted; of the three condensers at the last two tunnels two are in operation, and one is being defrosted. If the plant is used for coffee granules the operating pressure can be between 0.2 and 0.6 mbar, depending on the grain size distribution and the type of trays used. Besides aroma, color, bulk density, and cost the stability of the grains against abrasion is a quality which must be achieved.

Figure 46. Granulating and sieving installation to produce a granulate of specified dimensions from frozen plates or large lumps. The mills can be seen in the background on top; the sieves can be seen in the lower part in front. The photograph was taken before installation in the cold room. (Photograph: Vibra Maschinenfabrik Schultheis GmbH & Co, D-6050 Offenbach am Main).

6.3. For Metal Oxides, Ceramic Powders

In the publications studied it is difficult to distinguish between laboratory and small-scale production. Several papers concentrate on the production of small uniform particles which sinter at relatively low temperatures to densities close to that of the solid material. The term “spray freeze-drying” is used in one way or an other.

In a typical laboratory experiment ITATANI et al. [28] describe a process called “ultrasonic spray freeze-drying (USFD)” with two injecting nozzles. The two components - $Ca(CH_3COO)_2$/(hydrolyzed)$PO(OCH_3)$ (CaPo) and $ZrOCl_2/YCl_3$ (ZrY) are introduced by a flow of He into two ultrasonic systems. The resulting droplets are simultaneously frozen on a LN_2-cooled bottle. After freezing, the chamber is closed by a cover and evacuated by a rotary and oil-diffusion pumps. After 90 h of freeze-drying and some hot pressing the compact had a relative density of ca. 95 %, and grains smaller than 0.5µm were dispersed on boundaries of grains with sizes of 1–2 µm. Other methods of spraying are described, but the method is the same: the product is sprayed into fine particles and then dried. The formation of frozen particles and their drying are, in all cases studied, two separate steps.

[Top of Page]

7. Economic and Social Aspects, Outlook

Freeze-drying provides society with stable medical products for humans and animals, and it facilitates food and beverage preparation in specific areas such as spices, soup ingredients, and coffee. Many drugs would not be commercially available if they could not be stored under the conditions which prevail in many parts of the world. Freeze-drying of penicillin has made its application possible, freeze-drying of blood serum saved many lives in World War II, and its freeze-dryed fractions are still used to-day. Freeze-dried food is a more a matter of convenience and quality. Spices, e.g., can be air dried, coffee can be spray dried, soups can be canned, but the final products do not meet the original qualities or are heavy for transport. Economical freeze-drying needs substantial investments and crews of well-trained operators. In the medical field the cost to qualify processes and machinery add a significant part to the capital and labor cost. Quality and sterility have to be paid for. If the expenditure is not paid for by the markets, the product will not appear. The freeze-drying of food requires economically large installations with high throughputs; it is always a compromise between cost of production and required quality.

In the future of freeze-drying one can expect:

1. A substantial increase in the production of freeze-dried drugs
2. More sophisticated development and application of freeze-drying production processes
3. New food products will be available not by technical developments, but from marketing strategies of food manufactures

These expectations are based on the following current (2003) knowledge:

1. Worldwide more sophisticated freeze-drying production plants are being built. They replace older equipment without CIP and SIP or whose optimum operating pressures and/or freezing temperatures are too high. The new plants mostly have a substantially higher capacity per charge and are increasingly automatically loaded and unloaded. With lower temperatures during freezing and at the sublimation front of the ice (T_{ice}), the necessity of a uniform temperature distribution increases.
2. The development steps of a freeze-drying process are today often governed by trial and error; the transfer of process data to production is mostly based on incomplete data for the pilot and the production plants. In particular the influence of heat transfer and the flow of water vapor in both plants is not taken into account for process transfer. The process data will have to be measured and controlled by the actual data during the process and not by a predetermined time-temperature and time-pressure relations.
3. The qualification and validation of modernized or new processes and plants is time- and labor-intensive; therefore, points (1) and (2) will take time for their introduction; the effort is usually only justified for new products or production plants. On the other hand, the idea of a freeze-drying plant without low pressure (high vacuum), which has been raised again and again, will not become more feasible than it is today; the basic reasons for this are explained, e.g., in [7, section 1.2.6]. The other question —“why not make the process continuous”— can not be so easily dismissed (food is freeze-dried continuously). The main problems to be solved are sterility and abrasion during transport. Vacuum locks, different pressures during MD and SD, and condenser configurations could be possible. Products which could be sterilized after drying might be an answer to the first problem, if such products could be developed. Abrasion-free transport on air cushions requires a nonvacuum process; a magnetic field for support and transport seems to be conceivable, but the electrical energy to support it would require ca. 20 V in vacuum or installation outside the vacuum region. With all these “ifs” the question is “why”. The loading and unloading equipment and time can be dispensed with, but the drying time will not be shorter, and breakage of a vial may require stopping the process, emptying of the plant, and renewed start up, which alone takes the time of a full drying cycle. In food freeze-drying aluminum trays are used for bulk freeze-drying. Even if drugs could be sterilized after drying, the problem of dosage still remains. The end question may not be “why” but “who” is willing to invest the money for the development of a continuous plant for drugs, given the mentioned uncertainties and advantages that are difficult to

define.

4. Technical solutions for today's food freeze-drying of are many years old, sometimes one generation. They could be improved with modern technology. Only if new product ideas are developed and their marketing success is likely can one imagine the development of a new generation of food freeze-dryers. Otherwise it might be more economical to repeat proven plant designs with some engineering improvements.

The attempts to replace freeze-drying for certain drugs by other drying processes are sometimes described in the literature (estimated in 1 ‰ of all freeze-drying publications in the last few years). Solutions for replacement may be found (as for penicillin); newly developed drugs to be freeze-dried seem to outweigh those which can be dried with out freeze-drying. Overall an increase in the number of freeze-drying installations can be expected.

Abbreviations and symbols

av: average data

BTM: barometric temperature measurement

***bl* μ:** permeability of water vapor through the dried product, kg h^{-1} m^{-1} $mbar^{-1}$

CA: capacitive vacuum gauge

DR: desorption rate, desorbed water in % of solids per hour, %/h

DSC: differential scanning calorimetry

***d*:** thickness of layer, diameter, cm, m

d*p*: pressure rise, mbar

d*t*: time of d*p*, s, h

dW: desorbable water in % of solids, %

ER: electrical resistance, Ω

K_{su}**:** heat transfer coefficient from the heating medium to the freezing zone, kJ m^{-2} h^{-1} °C^{-1}

K_{tot}**:** heat transfer coefficient from the heating medium to the sublimation front, kJ m^{-2} h^{-1} °C^{-1}

LN_2: liquid nitrogen

LS: sublimation energy of water, kJ/kg

***l*:** length, m, cm, mm, μm, nm

λ_g**:** thermal conductivity of frozen product, kJ cm^{-1} s^{-1} °C^{-1}

λ_{tr}**:** thermal conductivity of dried product, kJ cm^{-1} s^{-1} °C^{-1}

MD: main drying, sublimation drying

m_{fest}**:** mass of solids, g

Δm: fraction of frozen water, kg/kg

NMR: nuclear magnetic resonance

p_c: controlled operating pressure during MD, mbar

p_{ch}: pressure in the drying chamber, mbar

p_{co}: pressure in the condenser, mbar

p_{MD}: pressure during MD, mbar

p_{pg}: pressure of permanent gases, mbar

p_s: saturation vapor pressure, mbar

RG: residual moisture content measured by gravimetric method, % of solids

RM: residual moisture content, % of solids

r: radius, m, cm

ϱ_g: density of frozen product, kg/m^3, g/cm^3

SD: secondary drying

SEM: scanning electron microscopy

sd: standard deviation

T_c: collapse temperature, °C

T_{co}: condenser temperature, °C

T_g: glass transition temperature, °C

$T_{g'}$: glass transition temperature if all freezable water is crystallized, °C

T_{tot}: time-weighted average of temperature difference (T_{sh}–T_{ice}) during MD, °C

T_{ice}: temperature of ice at the sublimation front, °C

$T_{ice/n}$: sum of all n T_{ice} measurements divided by n, °C

T_{MD}: temperature during MD, °C

T_{pr}: product temperature, °C

T_{sh}: shelf temperature, °C

TM: heat conductivity vacuum gauge

t_f: freezing time, h, min

t_{MD}: secondary drying time, h

t_{SD}: secondary drying time, h

UFW: “unfreezable water”, % of total water

V_{ch}: volume of a drying chamber, m^3, L

ζ_w: fraction of water in the initial product, kg/kg

7.4. Processes
7.5. Process Validation
8. Applicability of GMP
9. GMP in API Process Development

[Top of Page]

1. Introduction

Good Manufacturing Practices (GMPs) represent the minimum requirements that must be satisfied when producing pharmaceuticals for human or veterinary use [1]. They mandate a high degree of control over all stages of the manufacturing process, from ordering the raw materials through to packaging and dispatching the finished goods. All aspects of production must be described in written procedures, and all production activities must be thoroughly documented as they are carried out.

GMPs may be viewed as the third element of a trio of “GXP” regulatory requirements, which comprise also Good Laboratory Practice (GLP) and Good Clinical Practice (GCP). GLP mandates certain standards for laboratories engaged in scientific studies of new drug candidates, e.g., to obtain toxicological or pharmacological data from studies on animals. The GLP regulations enforced in the USA are detailed in part 58 of the Code of Federal Regulations Title 21. The equivalent requirements in the European Union are covered in Section II of the annex to Council Directive 87/18/EEC, amended by Commission Directive 1999/11/EC. GCP refers to basic principles in the conduct of clinical trials involving human patients. Within Title 21 of the U.S. Code, these issues are dealt with in parts 50, 54, and 56. The EU is currently harmonizing requirements for clinical trials across all its member states. A Clinical Trials Directive was published in the Official Journal of the European Communities in May 2001, and all states are expected to be in compliance with this by 2004. GMP governs the actual manufacturing of drug substances and products; it is mandatory for the production of clinical supplies of novel drugs and for commercial supplies of approved drugs.

This article will mainly focus on the GMP requirements at the stage of chemical manufacturing — the manufacturing of “drug substances” or “active pharmaceutical ingredients” (APIs). The requirements for “drug products” — i.e., the dosage forms such as tablets, capsules, injectable vials, etc — and for the manufacture of medical devices, are different and generally more stringent, but these are not discussed in detail here.

One of the principle reasons for GMP is to ensure the consistency of drug manufacturing processes. It avoids the situation, prevalent in other areas of the chemical industry, in which the final testing performed on individual batches or units is the

main, or even the sole, determinant of product quality. Reliance on testing alone is not appropriate for pharmaceuticals because:

Testing is only performed on a small sample, which may not be completely representative.
Defective products which escape detection at the testing stage constitute a grave danger to consumers (patients).
Patients themselves have no means of detecting such defects and cannot rectify them.

Testing cannot be relied upon to detect all failures in the manufacturing process; some defective batches will always get through. In some situations, such as the manufacture of socks or compact discs, this may not be a serious concern, since it causes only mild irritation to the 0.1 % (say) of customers who inadvertently purchase the defective objects, and they then have the option of returning them to the shop. With pharmaceuticals, the consequences of 0.1 % of patients receiving defective medicines are potentially far more serious. Therefore, GMP places as much emphasis on Quality Assurance — preventing the failures in the first place — as on Quality Control [2].

Even under the most tightly-regulated GMP regime, manufacturing problems and failures still occur, so Quality Control is still important. But under GMP, such failures should not simply be accepted as an unavoidable “act of God”. Rather they should be thoroughly investigated to determine the underlying causes and to prevent their recurring. By gradually eliminating the causes of failure, the incidence of failure should decline over time, and greater confidence in the consistency of the process is generated.

Under GMP, manufacturers are also expected to embrace novel technologies as they emerge, where these offer significant quality improvements. Examples are the use of more accurate engineering control systems, surface coating materials which are easier to clean and sanitize, and more sensitive techniques for chemical analysis. It is not that innovation must be embraced for its own sake; the cost of a novel measure must be considered in relation to the quality improvement it brings. However, the industry “benchmark” standards do evolve over time, hence prevalent use of the acronym cGMP (current GMP).

[Top of Page]

2. GMP in the USA

GMPs first emerged as a legal requirement in the USA in 1962, following substantial amendments to the 1938 Food, Drug, and Cosmetic Act, and since that time they have been enforced by the FDA (Food and Drug Administration) [3], [4]. The GMP regulations are detailed in part 211 of the Code of Federal Regulations Title 21. The current version has been in force since 1978, but FDA announced a major review of their GMP policy in 2002, which is expected to take about two years. The 21CFR211 regulations are legally binding requirements for all pharmaceutical manufacturers in the USA; drugs imported from other countries must also have been manufactured according to these standards.

Part 211 is divided into 11 subparts, covering the following:

A. General Provisions: Scope, Definitions.
B. Organization and Personnel: Responsibilities of quality control unit; Personnel qualifications; Personnel responsibilities; Consultants.
C. Buildings and Facilities: Design and construction features; Lighting; Ventilation, air filtration, air heating and cooling; Plumbing; Sewage and refuse; Washing and toilet facilities; Sanitation; Maintenance.
D. Equipment: Equipment design, size, and location; Equipment construction; Equipment cleaning and maintenance; Automatic, mechanical, and electronic equipment; Filters.
E. Control of Components and Drug Product Containers and Closures: General requirements; Receipt and storage of untested components, drug product containers, and closures; Testing and approval or rejection of components, drug product containers, and closures; Use of approved components, drug product containers, and closures; Retesting of approved components, drug product containers, and closures; Rejected components, drug product containers, and closures; Drug product containers and closures.
F. Production and Process Controls: Written procedures; Deviations; Charge-in of components; Calculation of yield; Equipment identification; Sampling and testing of in-process materials and drug products; Time limitations on production; Control of microbiological contamination; Reprocessing.
G. Packaging and Labeling Control: Materials examination and usage criteria; Labeling issuance; Packaging and labeling operations; Tamper-resistant packaging requirements for over-the-counter (OTC) human drug products; Drug product inspection; Expiration dating.
H. Holding and Distribution: Warehousing procedures; Distribution procedures.
I. Laboratory Controls: General requirements; Testing and release for distribution; Stability testing; Special testing requirements; Reserve samples; Laboratory animals; Penicillin contamination.
J. Records and Reports: General requirements; Equipment cleaning and use log; Component, drug product container, closure, and labeling records; Master production and control records; Batch production and control records; Production record review; Laboratory records; Distribution records; Complaint files.
K. Returned and Salvaged Drug Products: Returned drug products; Drug product salvaging.

In the mid 20th century FDA's enforcement activities concentrated mainly on secondary (dosage-form) manufacturing, and indeed the GMP regulations [5] were drafted entirely from the drug-product perspective. However, technically the U.S. legislation does not distinguish between drug products (dosage forms) and drug substances (APIs), and since the early 1980s FDA has increasingly emphasized the application of GMPs to API manufacturing also, using the 21CFR211 regulations as guidelines in their inspections of API plants. Initially, this was a source of much confusion and frustration among API manufacturers, because the regulations fail to take account of the very different manufacturing environment prevalent in API production plants, as opposed to pharmaceutical formulation plants. In practice, different inspectors had widely different expectations of how far the drug product regulations could reasonably be applied.

In 1987, FDA published their “Guide to Inspection of Bulk Pharmaceutical Chemicals” (revised 1991). But while this provided manufacturers with some useful insights into FDA's principal areas of concern, it is purely an internal agency document with no legal or regulatory status. Only in the late 1990s did official FDA Guidelines on APIs begin to emerge. Two draft versions were produced in 1996 and 1998, and the final version was endorsed in 2001. This final version is identical with the “Q7A Good Manufacturing Practice Guidance for Active Pharmaceutical Ingredients”, drafted by the International Conference on Harmonization (ICH), and thus is relevant not just in the USA but throughout the world [6].

FDA is required by its statutes to inspect all drug manufacturing facilities for GMP compliance once every two years — not just USA-based companies, but also foreign facilities where products are manufactured for export to the USA. Recently, however, the true inspection rate has declined to nearer once every six years, and the agency has been seeking ways to rationalize its inspectional work by concentrating on companies or areas of manufacturing which present the highest risks. Where an inspection reveals that a firm is not following the GMP regulations, its products may be deemed to be “adulterated”, regardless of whether or not they are physically contaminated or otherwise defective. Thus they may be barred from entry to the USA, seized, or even destroyed. In extreme cases, criminal penalties may be applied to the company and to individual company executives. In recent years fines of up to $500 million have been levied against several companies for GMP violations. However, most violative practices are associated with drug products rather than APIs.

[Top of Page]

3. GMP in the EU

In Europe, responsibility for drug regulation is split between various bodies: some national, some supranational. Until the 1990s, each country was essentially autonomous, maintaining its own agencies for drug approvals and inspections. For example, in the UK the Medicines Control Agency (MCA) fulfilled these functions. Each national agency operated according to its own procedures. The situation changed in 1995 with the establishment of the European Agency for the Evaluation of Medicinal Products (EMEA). EMEA now coordinates the approval process for new human and veterinary drugs throughout the EU, but most of the work involved is still carried out by the individual national agencies, now following centrally agreed procedures. In matters of GMP and inspections, a degree of international cooperation has existed for much longer, in the form of the Pharmaceutical Inspection Convention (PIC). Originally established in 1970 under the auspices of the European Free Trade Association (EFTA), it now comprises 24 (mostly European) countries who recognize the validity of each other's drug inspection procedures, with the aim of cutting down on unnecessary transnational inspections. Attempts have been made to agree mutual recognition procedures with the USA as well, but to date — in spite of a Mutual Recognition Agreement concluded in 1997 — these have been unsuccessful.

The European approach to GMP has been different from the American experience, in that there has been less emphasis on legislative enforcement. Rather, government inspectorates have sought to work in cooperation with manufacturers to encourage improvement in quality standards, in contrast to the adversarial and “investigative” approach associated with the FDA. The first GMP guide to be produced in the UK was published in 1971. Known as the “Orange Guide” after the color of its cover, this was originally intended as a Code of Practice for pharmaceutical manufacturers. Similar codes appeared in other European countries over the next few decades. From the late 1980s, the guidelines of the EEC, later the EU, were published, and eventually superceded those of individual member states. The Orange Guide continues to be published in the UK (latest edition 1997), but is now a straight reproduction of the European text [7].

The Orange Guide covers the same ground as the Part 211 regulations in the USA, but in a different order, and in somewhat greater detail. It is divided into nine chapters coving the following topics:

- One *Quality management*: Principle; Quality Assurance (QA); Good Manufacturing Practice (GMP) for medicinal products; Quality Control (QC).
- Two *Personnel*: Principle; General; Key personnel; Training; Personnel hygiene.
- Three *Premises and equipment*: Principle; Premises; General Production area; Storage areas; Quality Control (QC) areas; Ancillary areas; Equipment.
- Four *Documentation*: Principle; General; Documents required; Specifications; Starting and packaging materials; Intermediate and bulk products; Finished products; Manufacturing formula and processing instructions; Packaging instructions; Batch processing records; Batch packaging records; Procedures and records for Receipt, Sampling, Testing; Other.
- Five *Production*: Principle; General; Prevention of cross-contamination in production; Validation; Starting materials; Processing operations: intermediate and bulk products; Packaging materials; Packaging operations; Finished products; Rejected, recovered and returned materials.
- Six *Quality Control*: Principle; General; Good Quality Control Laboratory Practice; Documentation; Sampling; Testing.
- Seven *Contract manufacture and analysis*: Principle; General; The Contract Giver; The Contract Acceptor; The Contract.
- Eight *Complaints and product recall*: Principle; Complaints; Recalls.
- Nine *Self-inspection*: Principle

Additionally, there are 14 annexes, dealing with: Manufacture of sterile medicinal products, Manufacture of biological medicinal products for human use, Manufacture of radiopharmaceuticals, Manufacture of veterinary medicinal products other than immunologicals, Manufacture of immunological veterinary medicinal products, Manufacture of medicinal gases, Manufacture of herbal medicinal products, Sampling of starting and packaging materials, Manufacture of liquids, creams and ointments, Manufacture of pressurized metered dose aerosol preparations for inhalation, Computerized systems, Use of ionizing radiation in the manufacture of medicinal products, Manufacture of investigational medicinal products, Manufacture of products derived from human blood or human plasma.

GMP only became a legal requirement for drug product manufacturing throughout the EU in 1992, 30 years after its

imposition in the USA. At that time it did not strictly extend to API manufacturing, although API manufacturers were increasingly encouraged to follow GMP principles, and inspectorates took an increasing interest in their activities. Only with the ratification of the international Q7A guidelines in 2001 did APIs finally become officially regulated by European law.

[Top of Page]

4. GMP in the Wider World

The Q7A guideline is also official policy in Japan, the third main participant in the ICH process. Elsewhere in the world, most developed countries (e.g., Australia, Canada) have their own GMP regulations, but where these affect APIs they are rarely significantly different from Q7A. Developing countries have tended to adopt the guidelines from the WHO, which represent basic minimum standards for local pharmaceutical manufacturing, but are not considered suitable for the export of drugs elsewhere.

[Top of Page]

5. The ICH Q7A Guideline

The International Conference on Harmonization (ICH) is a joint forum between representatives of the regulatory authorities and the pharmaceutical industry from the USA, the EU, and Japan. It was established in 1990 with a remit to harmonize the technical standards for the registration of pharmaceuticals across the world. The main themes which it addresses are Quality, Safety, and Efficacy. Over the years it has developed many guidelines on matters such as impurities, residual solvents, clinical safety studies, stability testing, analytical validation, quality of biotechnological products, and much more. There has also been progress towards a “Common Technical Document” to serve as a new drug application format throughout the world.

Although GMP is not strictly a drug registration issue, and so is slightly outside its main remit, ICH became interested in this subject in the late 1990s. By this time, GMP standards for drug products were well advanced throughout the developed world, but were only enforced for APIs in the USA. FDA had issued their first “Guidance for Industry” on API manufacturing as a discussion draft in 1996, with a second draft appearing in 1998 after some consultation with industry representatives. Simultaneously, guidelines were being developed by the Pharmaceutical Inspections Convention (PIC) [8], the European Federation of Pharmaceutical Industries and Associations (EFPIA) [9] and the Pharmaceutical Research Manufacturers of America (PhRMA) [10]. ICH adopted these frameworks as the basis for their Q7A international guidelines, which first appeared in draft format in 2000, achieving final endorsement in 2001. Shortly thereafter, Q7A was officially adopted by the regulatory authorities in the USA, Europe, and Japan.

In the USA, Q7A has the status of a guideline, rather than a legally enforceable regulation. It represents FDA's current thinking on the subject and describes practices which will be acceptable to them. But conformance with the guideline recommendations is not mandatory; companies may adopt alternative approaches if they can be justified as consistent with the 21CFR211 regulations.

In any case, the guideline does not prescribe or recommend any specific measures, procedures, specifications, or controls; the emphasis is rather on ensuring that companies establish these for themselves. The word “appropriate” appears throughout, emphasizing that requirements and constraints may vary from one company to another. The guideline sets out the goals to be attained, but recognizes that they may be reached by different pathways. Each company is expected to define its own approaches and to demonstrate that these will succeed in meeting the prescribed goals.

The main topics covered by the Q7A Guideline are:

- Quality Management
- Personnel
- Buildings and Facilities
- Process Equipment
- Documentation and Records
- Materials Management
- Production and In-Process Controls
- Packing and Identification Labeling of APIs and Intermediates
- Storage and Distribution
- Laboratory Controls
- Validation
- Change Control
- Rejection and Re-Use of Materials
- Complaints and Recalls
- Contract Manufacturers and Laboratories
- Agents, Brokers, Traders, Distributors, Repackers and Relabelers.

There is also specific guidance for APIs manufactured by cell culture or fermentation and for APIs used in clinical trials.

[Top of Page]

6. Quality Management

For an organization to be compliant with cGMP, the most fundamental requirement is to have an effective quality management structure. Quality should be the responsibility of all persons involved in manufacturing, but the system must be defined and overseen by an independent Quality Unit, which is separate from all production activities. The manager of this Quality Unit should report to a senior level of the organizational hierarchy, and should not be subordinate to the production manager. The quality unit should be involved in all quality-related matters, and should review and approve all quality-related documents.

The quality unit should fulfill the functions of quality control (QC) and of quality assurance (QA), though these may be organized as separate units if desired – depending on the size and structure of the company. The QC function normally comprises the analytical work carried out to ensure that specifications are met — e.g. for raw material quality, equipment cleanliness or air quality. QA has a more wide-ranging role and has been defined (in Q7A) as “the sum total of the organized arrangements made with the object of ensuring that all APIs are of the quality required for their intended use and that quality systems are maintained”. The quality unit should have defined responsibilities, as detailed in the guidelines, including the responsibility to release or reject batches of the final APIs.

One important QU responsibility is to ensure that internal audits, or self-inspections, are regularly performed to determine whether established procedures are being followed and whether the cGMP regulations and guidelines are being observed. The audit findings and/or corrective actions should be documented and brought to the attention of responsible management.

Regular quality-reviews of APIs should be conducted at least annually, comprising in-process control and test results, batch failures, deviations, nonconformances, process or analytical changes, stability results, complaints, and returns. The results of these reviews should be evaluated and an assessment made as to whether any corrective action is required.

The emphasis that GMP places on Quality Management invites comparison with international quality standards such as ISO 9000, which offer much useful advice on the construction of a logical Quality System [11]. However, ISO 9000 is a generic standard, intended to be applied throughout all areas of industry and commerce, and does not specifically address the peculiar needs of the pharmaceutical industry. While it covers many of the same themes as GMP, such as the emphasis on management responsibility, resource management, product and service realization, measurement, analysis, and improvement, other important areas are missing, e.g., hygiene and sanitation requirements, which would not necessarily be relevant in other branches of industry. Under ISO 9000 the requirement is mainly to have written policies covering the relevant elements; it is left mainly to companies' own discretion what these policies should be. The GMP Guidelines tend to be much more prescriptive. Thus ISO 9000 registration may be a useful starting point for a company to achieve GMP status, but it is neither a necessary nor a sufficient condition.

[Top of Page]

7. Principal Requirements of GMP

The full text of the Q7A guideline is freely available from the FDA website [12], so only a brief summary is presented here. The main provisions can be divided into requirements for Personnel, Materials, Premises and Equipment, and Processes.

7.1. Personnel

Personnel are often the most significant source of variance in a process, and most failures can ultimately be traced to human errors. A drug manufacturer should therefore employ an adequate number of personnel with the necessary qualifications and practical experience to perform and/or supervise the required tasks. The structure of the company should be set out clearly in an organization chart, and all personnel should have specific duties recorded in written job descriptions. Training in the particular operations that the employee performs, and in the cGMP regulations that relate to his/her function, should be conducted regularly by qualified instructors. Records of such training should be maintained, and its effectiveness should be periodically assessed. Appropriate clean protective apparel should be provided, and staff should practice good sanitation and health habits.

7.2. Materials

All process materials must be carefully controlled to ensure they are only used in those processes for which they have been approved. This means maintaining proper storage facilities, where clear distinctions are made between materials which are quarantined, approved, or rejected/returned. Appropriate specifications should be developed for all starting materials, reagents, processing aids, solvents, water, and primary packaging materials, as well as for the final APIs and key intermediates. Each individual batch or lot should be uniquely identified and evaluated against its specifications before being approved for use in any process. The evaluation should normally be carried out by the quality unit; however, for some of the earlier less critical manufacturing steps, it may be performed by production personnel, following QU-approved procedures. All incoming materials should be sampled, and at least one identity test performed. In many cases it is acceptable to rely on a supplier's Certificate of Analysis as evidence of the required quality, as long as confidence in that supplier can be justified on the basis of a quality audit or other evaluation process and of satisfactory experience. Randomly selected lots of all incoming materials should be subjected to full specification testing from time to time. Whenever a material is used in a process, its lot number and the precise amount dispensed should be recorded on the batch production record, so that all materials are traceable back to their original sources. Records should also be kept on the disposition of each lot.

7.3. Buildings, Facilities, and Process Equipment

Buildings and facilities used in the manufacture of intermediates and APIs should be located, designed, and constructed to facilitate cleaning, maintenance, and appropriate operations, and to minimize the potential for contamination. There should be defined areas, or other control systems, for distinct operations such as receipt, sampling, quarantine, storage,

processing, packaging, and laboratory activities. Adequate lighting should be provided in all areas. Adequate ventilation, air filtration, and exhaust systems are required for those environments where the final API is isolated, dried, or packaged. Such areas should have smooth, continuous, and impermeable surfaces, with no sharp corners. API processes should ideally be physically segregated from one another; if this is not possible, then adequate procedures should be established which prevent cross-contamination.

Utilities such as steam, gas, compressed air, heating, ventilation, and air-conditioning should be qualified and appropriately monitored wherever they may affect product quality. Drawings for these systems should be available, and appropriate operating limits should be established.

All processing equipment should be of appropriate design and adequate size, and suitably located for its intended use, cleaning, sanitation, and maintenance. Any surfaces which directly contact the raw materials or products should be constructed of unreactive materials which will not adversely affect the quality of the API (e.g., steel equipment may not be appropriate for processing corrosive materials such as hydrochloride salts). All instruments should be regularly calibrated to ensure they consistently operate within defined tolerances.

Critical equipment and facilities should be formally qualified to demonstrate their suitability for the required operations and their conformance to predetermined specifications. Qualification will normally be conducted in different phases, beginning with a Design Qualification (DQ), in which the manufacturer's designs, blueprints, and specifications are compared with the user's own requirements to assess whether the basic concept will meet the defined process demands. Once the item has been installed and commissioned, it should go through the Installation Qualification (IQ) stage, which is a checklist to confirm that all the necessary functionality (switches, gauges, electrical connections, etc.) is present and of a suitable standard. The next stage is an Operational Qualification (OQ), in which the equipment is set to work on a typical task or process (usually employing inert materials), and details of its performance are collected and assessed. Finally, in the Performance Qualification (PQ), a trial run of a real process is conducted. (This PQ may be performed as part of the validation of that particular process.)

All equipment should be subject to a regime of planned preventative maintenance, to ensure that it continues to operate within its specifications, and to detect and rectify any potential problems at an early stage before they cause any batch failures.

In some cases it may be necessary to dedicate the equipment to particular processes, most notably for the production of highly sensitizing products such as penicillins.

Equipment should normally be cleaned to a satisfactory standard after each individual batch to prevent cross-contamination between batches and, most importantly, between different products. Equipment dedicated to one process or used for a multibatch campaign of the same product may be cleaned less frequently, but this should be justified on a case-by-case basis.

Companies are expected to establish their own cleanliness criteria based on an assessment of their own circumstances. Normally the criteria will include the requirement for no visible residue on the equipment surface. Where the surface is not completely accessible for visual inspection, some indirect means should be established, such as a rinse test or a swab test, with defined residue limits. Such limits should be rational, practical, achievable, and verifiable. For example, some companies operate on the 10 ppm principle, whereby limits are set to ensure that the following product cannot be contaminated with more than 10 ppm of the previous product. Other companies set limits to ensure that the maximum daily dose of the following product cannot be contaminated by more than 0.1 % of the minimum daily dose of the previous product.

Cleaning after each process should be defined in written procedures, which should be validated to ensure that they consistently achieve the defined standards. Cleaning validation involves identifying the areas of the equipment which are most difficult to clean and demonstrating that they are in fact cleaned to the required standard over a number of consecutive (usually three) runs. This may involve dismantling the equipment to some extent to reach otherwise inaccessible areas. However, cleaning validation need only be performed on a “worst-case” basis, that is, on those processes which are judged to present the greatest cleaning difficulties [13].

7.4. Processes

The production of each batch of API or intermediate should be closely documented to provide as complete a record as possible of the circumstances of its manufacture. To ensure uniformity from batch to batch, master production instructions should be prepared, dated, and signed by one person and independently checked, dated, and signed by another person in the quality unit. The master instructions should give details of all process materials required, including packaging and labeling, with their quality specifications and amounts. The major production equipment should be specified, along with detailed production instructions, including sequences, allowable ranges for process parameters, sampling instructions, in-process controls, time limits for completion of individual steps, and expected yield ranges at appropriate phases. Each individual batch should conform as far as possible to these master instructions, with any deviations being recorded, investigated, and evaluated.

Each individual batch production record should identify the operators and supervisors involved with the batch, record equipment numbers, the dates and times of each critical operation, the lot numbers of each ingredient used and the precise amounts dispensed, the actual results recorded for critical process parameters and in-process controls, actual yields at appropriate phases, details of any process deviations, and results of release testing.

7.5. Process Validation

A formal validation is required for all operations determined to be critical to the quality and purity of the API [14]. Process validation is often a very time consuming and laborious activity; therefore, many companies perform it only on the final

synthetic steps, relying on quality control and other GMP measures to assure the quality of the earlier, less critical intermediates. A written validation protocol should be established that specifies how the validation of a particular process will be conducted. This should identify the critical product attributes of the API (e.g., analytical specifications, physical form), and the critical process parameters (e.g., temperatures, stoichiometry) which may affect these attributes. For each critical parameter a normal operating range, a proven acceptable range, and, where appropriate, edge of failure limits, should be established. A series of consecutive validation runs (usually three) is then undertaken to establish that the process consistently falls within the defined ranges for each parameter and that the product consistently meets its quality specifications.

Validation studies should normally be completed before any commercial distribution of the API (Prospective Validation). For most new drugs, FDA approval will be withheld until the agency is satisfied that an adequate validation has been performed. In a minority of cases, an alternative approach (Concurrent Validation) may be more appropriate. For example, if the drug already has marketing authorization, its sales may continue while the validation studies are underway. (However, since validation has been a requirement since the late 1980s, there can be few drugs remaining in this category.) Another case would be where batches are made very infrequently because of low demand; in this situation the first batch may be approved and distributed before the validation is complete, the validation being resumed with the next batch. Concurrent Validation may also be used to justify approval of a single batch where there has been a substantial deviation from the established (validated) process. This would comprise detailed assessments of the impact of the deviation coupled with extra analytical investigations to ensure the quality of the drug substance. A third approach (Retrospective Validation) is mentioned in FDA guidelines, but increasingly discouraged. This involves no validation runs as such, but rather a detailed review of a large number (20–30) of consecutive historical batches, including any which have failed. This approach presupposes that sufficient details were collected at the time.

Once a process has been validated, strict controls must be enforced to prevent unauthorized changes. Any proposed changes to the process should be formally evaluated for the effect they may have on the critical quality attributes of the API. If a process change is judged to be major, i.e., it has the potential to influence the quality of the product, then its introduction should be preceded by a revalidation of the process. Minor changes which are judged unlikely to affect product quality may be implemented without formal revalidation, provided they give an equivalent input to the process. (For example, if the starting material is obtained from a new supplier, it should meet the same qualitative and quantitative specifications as that from the previous supplier.) Each process should be reviewed on a regular (perhaps annual) basis to assess how far it has shifted since its last validation, and a judgment should be made as to whether revalidation is required.

[Top of Page]

8. Applicability of GMP

GMP is expected to apply not only to the final API, but also to intermediate stages of the synthesis. But a significant regulatory burden is incurred by companies when lengthy syntheses are subject to regulatory review and GMP inspection. How far back in the synthesis GMP should reach remains a “gray area”. FDA has accepted that it is unreasonable to apply GMP concepts to the original progenitors of the API, which may have come from plants, mines, oil wells, or sea water. However, “it is reasonable to expect GMP concepts to start to become applicable at that point where a starting material enters a biological or chemical synthesis or series of processing steps where it is known that the end product will be a BPC (Bulk Pharmaceutical Chemical)” [15].

A key issue is therefore the definition of the “starting materials” for each synthesis. According to the Q7A guideline, these are materials which are “incorporated as a significant structural fragment into the structure of the API”. Starting materials may be purchased from an external supplier or contract manufacturer, or manufactured in-house, and accepted on the basis of conformance to an analytical specification; there is no requirement to observe GMP during their manufacture. Thus it is in the API manufacturer's interest to define the starting materials as late in the synthesis as possible. In the past, starting materials were normally expected to be commercially available substances with a variety of uses. Compounds produced specifically for the API synthesis were regarded as intermediates, and therefore subject to GMP. In practice, however, many such compounds were accepted by FDA as starting materials, after review on a case-by-case basis. The official FDA criteria for a starting material were [16]:

> It is a compound whose name, chemical structure, chemical and physical characteristics and properties, and impurity profile are well-defined in the chemical literature, or
> It is obtained by commonly known procedures (this applies principally to starting materials extracted from plants and animals, and to semisynthetic antibiotics).

More recently, commentators have criticized the vagueness of these criteria. PhRMA [17] has suggested as an alternative that a noncommercial substance should be regarded as a starting material if all of the following apply:

> It is a significant structural fragment of the drug substance.
> It has a well-characterized structure and well-defined purity profile (whether or not published in the open literature).
> Specifications exist which ensure appropriate control over downstream processing and drug substance quality.
> It is not the final intermediate, used in the step which generates the API molecule itself.

The argument is that the improvements in analytical technology over the past decade make it more reasonable to expect the quality attributes for starting materials to be readily identified and controlled.

Once the starting materials have been defined, all subsequent synthetic steps should be carried out under GMP, but this need not be at a uniform level:

"Although strict observance of GMPs, approaching or equaling those expected for finished drug products, may be expected in some types of bulk processes, in most others it is neither feasible nor required to apply rigid controls during the early processing steps. In all processes of this type, however, the requirements should be increasingly tightened according to some reasonable rationale. At some logical processing step, usually well before the final finishing operation, appropriate GMPs should be imposed and maintained throughout the remainder of the process." [15].

For example, the production of a very early intermediate may not require the ultralow residue limits on equipment, the process segregation, or the environmental control associated with the final step. While all intermediates should be evaluated and approved before further processing, for the earlier steps this may be performed entirely within the production department, whereas for the later steps the involvement of the quality unit is mandatory. All intermediates should be tested, but for *in situ* intermediates, this may involve no more than an in-process control. It is not necessary to set formal specifications for each intermediate; but companies should identify the critical stages of their syntheses at which specifications would be appropriate. The final intermediate is normally regarded as a major watershed in the synthesis — the point beyond which GMP controls should be significantly increased; here the specifications and tests should be nearly as stringent as those applied to the final API itself.

[Top of Page]

9. GMP in API Process Development

Pharmaceutical companies conduct a substantial amount of research into potential new therapeutic agents. Most candidate new drugs will never be marketed; they are rejected either for lack of safety, lack of efficacy, lack of bioavailability, or insufficient improvement over existing therapies. Nonetheless, they are tested on human volunteers before these decisions can be made. APIs intended for use in such clinical studies are expected to be produced according to appropriate GMP standards.

(Note that where the clinical trial material is produced on a small scale in a laboratory, its manufacture should still be subject to GMP, and not GLP. GLP relates to the conduct of laboratory studies, not to manufacturing on a laboratory scale.)

The application of GMP at the early investigative stage often gives rise to practical difficulties. By their nature, clinical investigations must be carried out before there has been time to develop the optimum manufacturing methods. One of the key features of GMP is process consistency, but this is the hallmark of a relatively mature process, and so is an unrealistic expectation during the development of that process. Often, the early studies use API prepared by the original discovery synthesis, which would not be appropriate for later large-scale manufacturing. It is difficult to set specifications for the starting materials or intermediates in the absence of long processing experience. Also, without validated analytical methods, it is difficult to be sure what impurities are present in the API. In some cases it is difficult to reproduce the physical form of the product on a consistent basis. Clinical APIs will normally be produced in chemical pilot plants, where the reactors are used for numerous processes, often only on one or two occasions each. Thus it is difficult to develop the validated cleaning methods which guarantee against cross-contamination.

There is therefore a need for much more process flexibility at the development stage than could be tolerated in commercial production. There must be more reliance on case-wise scientific judgment than on immutable specifications. But this increased flexibility is mitigated by the more detailed attention that can be given to the production of individual batches, the use of more highly qualified and experienced personnel, the more extensive testing carried out, and the relatively small number of patients involved in the studies.

The Q7A guideline recognizes that not all the controls it recommends are appropriate for the manufacture of clinical APIs, and makes some broad recommendations in Section XIX. This theme has also been developed in greater detail by the API Committee of CEFIC, the European Chemical Industries Council [18]. Their approach to GMP for API Development is based on the following principles:

- The product should be fit for its intended use, and the safety of any subject in the clinical trails should be guaranteed.
- All information relating to the quality of the product or process should be retrievable and reconstructable.
- Quality must be built into the process — the earlier the better.
- During the development of an API the GMP controls should increase.

During early development there may not even be a firm specification for the API itself. The principle generally observed is that its quality should be at least as good — and preferably better — than that used in the preclinical toxicology studies or previous clinical studies. In particular it should contain no new impurities which were not present in those previous batches.

GMP lays particular emphasis on the importance of good record keeping, and if anything this is even more vital in the early project stages (when processes are changing rapidly) than during commercial operations (when the processes are largely fixed). Information generated from the beginning of the project should therefore be constantly documented in development reports. These allow the project to develop in a logical scientific manner, and facilitate the validation of the process when it moves into commercial manufacturing.

But while it is necessary to exercise flexibility with process control issues during API development, there is no reason to be less stringent in areas such as housekeeping, cleanliness, record keeping, equipment maintenance, calibration or staff training. In these areas the standards in the pilot plant should be similar to those observed in a commercial API plant.

Abstract

The article contains sections titled:

1. Introduction
2. Examples of Reactions
2.1. Reductions Catalyzed by Oxidoreductases (E.C. 1)
2.1.1. Ketone Reduction with Whole Cells of *Neurospora crassa* (E.C. 1.1.1.1)
2.1.2. Ketoester Reduction with Cell Extract of *Acinetobacter Calcoaceticus* (E.C. 1.1.1.1)
2.1.3. Enantioselective Reduction with Whole Cells of *Candida sorbophila* (EC 1.1.X.X)
2.1.4. Production of Chiral α-Hydroxy Acids with D-Lactate Dehydrogenase (E.C. 1.1.1.28) from *Leuconostoc mesenteroides*
2.1.5. Converting Ketoacid Acetals to Acetal Amino Acids with L-Phenylalanine Dehydrogenase (PheDH, E.C. 1.4.1.20) from *Thermoactinomyces intermedius*
2.2. Oxidations Catalyzed by Oxidoreductases (E.C. 1)
2.2.1. Alcohol Oxidation with Whole Cells of *Gluconobacter suboxydans* (E.C. 1.1.99.21)
2.2.2. Kinetic Resolution by Oxidation of Primary Alcohols Catalyzed by Whole Cells from *Rhodococcus erythropolis* (E.C. 1.X.X.X)
2.2.3. Hydroxylation of Nicotinic Acid (Niacin) Catalyzed by Whole Cells of *Achromobacter xylosoxidans* (E.C. 1.5.1.13)
2.2.4. Reduction of Hydrogen Peroxide Concentration by Catalase (E.C. 1.11.1.6)
2.2.5. Bioconversion of *N*-Butylglucamine with Whole Cells of *Gluconobacter oxydans* (E.C. 1.1.99.21)
2.3. Hydrolytic Cleavage and Formation of C—O and C—N Bonds by Hydrolases (E.C. 3)
2.3.1. Kinetic Resolution of a Diester by Protease Subtilisin Carlsberg from *Bacillus sp*. (E.C. 3.4.21.62) ,
2.3.2. Kinetic Resolution of α-Amino Acid Amides Catalyzed by Aminopeptidase from *Pseudomonas putida* (E.C. 3.4.1.11)
2.3.3. Production of L-Methionine by Kinetic Resolution with Aminoacylase of *Aspergillus oryzae* (E.C. 3.5.1.14)
2.3.4. Synthesis of β-Lactam Antibiotics Catalyzed by Penicillin Acylase (E.C. 3.5.1.11)
2.3.5. Enantioselective Synthesis of an Aspartame Precursor with Thermolysin from *Bacillus proteolicus* (E.C. 3.4.24.27)
2.3.6. Hydrolysis of Heterocyclic Nitriles by Nitrilase/Hydroxylase from *Agrobacterium sp*. (E.C. 3.5.5.1)
2.3.7. Resolution of 3,3,3-Trifluoro-2-hydroxy-2-methylpropionamide with Amidase from *Klebsiella oxytoca* (E.C. 3.5.X.X)
2.4. Formation of C—C, C—O, and C—N Bonds by Lyases (E.C. 4)
2.4.1. Hydrocyanation of *m*-Phenoxybenzaldehyde with Oxynitrilase from *Hevea brasiliensis* (E.C. 4.1.2.39)
2.4.2. Synthesis of Carnitine Catalyzed by Carnitine Dehydratase in Whole Cells (E.C. 4.2.1.89)
2.4.3. Synthesis of L-Dopa Catalyzed by Tyrosine Phenol Lyase from *Erwinia herbicola* (E.C. 4.1.99.2)

2.4.4. Synthesis of Nicotinamide Catalyzed by Nitrile Hydratase from *Rhodococcus erythropolis* (EC 4.2.1.84) ,
2.4.5. Synthesis of Mandelic Acid with Nitrilase (E.C. 4.2.1.84) ,
2.5. Epimerization of Glucosamine Catalysed by Epimerase from *E. coli* (E.C. 5.1.3.8)
3. Outlook

This article focuses on the use of nonimmobilized biocatalysts for synthesis of fine chemicals in industry. More than 20 processes using isolated enzymes or suspensions are presented.

[Top of Page]

1. Introduction

Enzymes as homogeneous catalysts have found widespread application for the synthesis of fine chemicals, mostly due to their selectivity [1], [2]. Although some enzymatic approaches are clearly superior to classical chemical methods, only a few processes have reached larger scale industrial application [3, 7]. While the use of immobilized biocatalysts ⟶ is well known, this article focuses on the use of nonimmobilized biocatalysts in industrial fine-chemical synthesis. The term “nonimmobilized“ refers to biocatalysts not bound or absorbed on a support, i.e., isolated enzymes and suspensions of whole cells.

There are many prejudices against biotransformations in the chemical industry, the two most important of which are:

1. Biocatalysts are too expensive
2. Biocatalysts only work under mild conditions

The first is only true in part. If the cost per mole or unit weight is calculated then they are certainly expensive. For example, penicillin amidase costs $ 10 000/kg on a bulk scale. However, the cost contribution of penicillin amidase in the splitting of penicillin G is only $ 1 per kilogram of product [8]. In L-aspartic acid production the cost contribution of aspartase is even lower, namely, $ 0.1/kg. This demonstrates that not the absolute catalyst cost but the cost contribution of the catalyst to the final product cost has to be considered and compared. This is also true for chemical catalysts, e.g., the bulk price of BINAP is $ 40 000/kg [8]. Important parameters influencing the cost contribution are the total turnover number (moles of product per mole of catalyst) and the turnover frequency (moles of product per mole of catalyst and unit time).

The second prejudice, that biocatalysts only work in aqueous phase with low concentrations of starting material, is also only true in parts. The natural environment is in general the aqueous phase and ambient temperature. But the examples described below demonstrate that biocatalysts can also be applied in emulsions or even pure organic solvents (Table 1). Here very high concentrations can be reached, e.g., in the case of acrylamide up to 5.6 M.

Table 1. Highest concentrations applied in industrial biotransformations

E.C. no.	Enzyme	Substrate	Concentration	Medium
1.1.99.21	D-sorbitol dehydrogenase	1-amino-D-sorbitol (N-protected)	1.00 M	aqueous
4.2.1.2	fumarase	fumaric acid	1.00 M	aqueous
4.3.1.1	L-aspartase	fumaric acid	1.00 M	aqueous
3.4.21.62	subtilisin	phenylalanine isopropyl ester	1.20 M	aqueous
3.1.1.3	lipase	1-phenylethylamine	1.65 M	MTBE
3.5.2.6	β-lactamase	γ-lactam	1.83 M	aqueous
4.2.1.84	nitrile hydratase	adiponitrile	2.01 M	aqueous/organic
4.3.1.1	L-aspartase	fumaric acid	2.00 M	aqueous
4.1.1.12	aspartate β-decarboxylase	aspartic acid	2.50 M	aqueous
3.1.1.25	lactonase	pantolactone	2.69 M	aqueous
3.1.1.3	lipase	palmitic acid	3.10 M	2-propanol
3.1.1.3	lipase	cyclopentenyl ester	4.16 M	aqueous/organic
4.2.1.84	nitrile hydratase	acrylonitrile	5.60 M (product)	aqueous
4.3.1.5	L-phenylalanine ammonia lyase	*trans*-cinnamic acid	9.31 M (NH_3)	aqueous

What is generally considered as a drawback can often prove to be an advantage of biocatalysts over chemical catalysts, since the environmentally benign reaction conditions may lower the process costs by reducing expensive waste due to a higher atom efficiency and lower energy costs [9], [10]. Also, in most cases the number of reaction steps can be reduced

by avoiding protection/deprotection sequences.

[Top of Page]

2. Examples of Reactions

The examples presented here are mostly taken from [3]. Newer processes have been added as far as information was available. Information on the synthesis of the substrates and application of the products can be found in the references on the specific process. If available, the whole synthetic route in which the biotransformation is integrated is given. The enzymes involved, either in a whole cell or as an isolated catalyst, are mainly from the groups of oxidoreductases (E.C. class 1) and hydrolases (E.C. class 3). There are a few examples for lyases (E.C. class 4) and one example for an isomerase (E.C. class 5). The majority of processes involving oxidoreductases use whole cells due to the problem of cofactor regeneration. The examples are sorted in the order of the main enzyme classes (EC). The letter **E** denotes the biotransformation step in the synthetic schemes.

2.1. Reductions Catalyzed by Oxidoreductases (E.C. 1)

2.1.1. *Ketone Reduction with Whole Cells of Neurospora crassa (E.C. 1.1.1.1) [11-14]*

The key step in the synthesis of Trusopt, a topically active treatment for glaucoma, is the enantioselective reduction of 5,6-dihydro-6-methyl-4*H*-thieno[2,3*b*]thiopyran-4-one-7,7-dioxide (Fig. 1).

Figure 1. Synthesis of Trusopt (**5**) via enzymatic reduction (Astra-Zeneca)

1: biologically derived homopolymer, **2**: (*R*)-methyl 3-hydroxybutyrate, **3**: 5,6-dihydro-6-methyl-4*H*-thieno[2,3*b*]thiopyran-4-one 7,7-dioxide, **4**: 5,6-dihydro-4-hydroxy-6-methyl-4*H*-thieno[2,3*b*]thiopyran-4-one-7,7-dioxide, **5**: Trusopt (MK-0507), **E**: alcohol dehydrogenase (whole cells of *Neurospora crassa*).

TFAA = trifluoroacetic acid.

The biological route overcomes the problem of incomplete inversion of the *cis* alcohol in the chemical synthesis (Fig. 2). The reaction is carried out below pH 5 to prevent epimerization of the (6*S*)-methylketosulfone in aqueous media.

Figure 2. Chemical synthesis of Trusopt

DMS = dimethyl sulfide, TFAA = trifluoroacetic acid.

(*R*)-3-Hydroxymethyl butyrate (**1**), which is responsible for the stereochemistry of the methyl group in the sulfone ring, can be produced by depolymerization of biopolymers, e.g., Biopol from Zeneca, which is a natural polyester produced by some microorganisms as a storage compound.

2.1.2. *Ketoester Reduction with Cell Extract of Acinetobacter calcoaceticus (E.C. 1.1.1.1) [15-17]*

The biotransformation (Fig. 3) is an alternative to the chemical synthesis via the chlorohydrin and selective hydrolysis of the acyloxy group (Fig. 4). After final fractional distillation this synthesis has an overall yield of 41 %. The biotransformation has a yield of 92 %. The diketoester can be obtained as shown in Figure 5.

Figure 3. Synthesis of a key intermediate for anticholesterol drugs

Figure 4. Chemical synthesis of a key intermediate for anticholesterol drugs

CSA = camphorsulfonic acid, LiHMDS = lithium hexamethyldisilazide, NMP = *N*-methyl-2-pyrrolidone.

Figure 5. Synthesis of 6-benzyloxy-3,5-dihydroxyhexanoic acid ethyl ester

6-Benzyloxy-(3*R*,5*S*)-dihydroxyhexanoic acid ethyl ester is a key chiral intermediate for anticholesterol drugs that act by inhibition of hydroxymethylglutaryl coenzyme A (HMG CoA) reductase.

2.1.3. *Enantioselective Reduction with Whole Cells of Candida sorbophila (EC 1.1.X.X) [18-20]*

Here the biotransformation (Fig. 6) is preferred over the chemical reduction with commercially available asymmetric catalysts (BH_3- or noble-metal-based), since with the chemical catalysts the desired high enantiomeric excess (e.e. > 98 %, 99.8 % after purification) is not achievable. Since the ketone has only very low solubility in the aqueous phase, 1 kg ketone is added as solution in 4 L of 0.9 M H_2SO_4 to the bioreactor. The bioreduction is essentially carried out in a two-phase system consisting of the aqueous phase and small droplets composed of substrate and product. The downstream processing consists of multiple extraction steps with methyl ethyl ketone and precipitation induced by pH titration of the pyridine functional group (pK_a = 4.66) with NaOH. The (*R*)-amino alcohol is an important intermediate for the synthesis of β-3-agonists that can be used for obesity therapy and to decrease the level of associated type II diabetes, coronary artery disease, and hypertension.

Figure 6. Synthesis of a key intermediate for a β-3-agonist (Merck Research Laboratories)

EDC = *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride MTBE = methyl *tert*-butyl ether.

2.1.4. *Production of Chiral α-Hydroxy Acids with D-Lactate Dehydrogenase (E.C. 1.1.1.28) from Leuconostoc mesenteroides [21]*

In a membrane reactor (*R*)-3-(4-fluorophenyl)-2-hydroxypropionic acid is produced in a continuous process with high enantioselectivity (e.e. > 99.9 %) and a high space–time yield (560 g L^{-1} d^{-1}). The biotransformation was favored since an alternative chemical route yielded the alcohol in varying selectivity (78–92 % e.e.).

D-Lactate dehydrogenase (D-LDH) from *Leuconostoc mesenteroides* was favored over D-LDH from *Staphylococcus epidermidis* for economic reasons. The cofactor NADH was regenerated by oxidizing formate to carbon dioxide with formate dehydrogenase from *Candida boidinii* (Fig. 7). The product was obtained in good yield (80–90 %) and converted to the methyl ester for the determination of optical purity (e.e. > 99.9 %). The process is designed for multikilogram scale. The product is a precursor for a potential rhinovirus protease inhibitor.

Figure 7. Synthesis of a chiral α-hydroxy acid (Pfizer Global Research and Development)

2.1.5. *Converting Ketoacid Acetals to Acetal Amino Acids with L-Phenylalanine Dehydrogenase (PheDH, E.C. 1.4.1.20) from Thermoactinomyces intermedius [22-24]*

The amino acid acetal is a precursor for Omapatrilat, an antihypertensive drug, which inhibits the angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). The synthesis is carried out in 16 000 L batch reactions with heat-dried *E. coli* cells containing the cloned and overexpressed PheDH from *Thermoactinomyces intermedius* and the formate dehydrogenase from *C. boidinii* for cofactor regeneration (Fig. 8). Yield (97 %), conversion (97 %), and optical purity of the product (e.e. > 99 %) are very high.

Figure 8. Synthesis of an acetal amino acid (Bristol Myers Squibb)

2.2. Oxidations Catalyzed by Oxidoreductases (E.C. 1)

2.2.1. *Alcohol Oxidation with Whole Cells of Gluconobacter suboxydans (E.C. 1.1.99.21) [25-27]*

In 1923 the bacterium *Acinetobacter suboxydans* was isolated, and starting in the mid-1930s was used for the industrial oxidation of L-sorbitol to L-sorbose in the Reichstein–Grüssner synthesis of vitamin C [28]. Bayer uses the same type of reaction, but instead of *Acinetobacter* the bacterium *Gluconobacter suboxydans* is used in the oxidation of *N*-protected 6-

amino-L-sorbitol to the corresponding 6-amino-L-sorbose, which is an intermediate in the production of miglitol (Fig. 9). 1-Desoxynojirimycin is produced by chemical intramolecular reductive amination of 6-amino-L-sorbose. In contrast, the published chemical synthesis of 1-desoxynojirimycin and its derivatives requires multiple steps and laborious protecting-group chemistry. Miglitol and derivatives thereof are pharmaceuticals for treatment of carbohydrate metabolism disorders (e.g., diabetes mellitus).

Figure 9. Synthesis of key intermediate for miglitol (Bayer)

1: 1-amino-D-sorbitol, **2**: 6-amino-L-sorbose (*N*-protected), **E**: D-sorbitol dehydrogenase (whole cells of *Gluconobacter suboxydans*).

2.2.2. *Kinetic Resolution by Oxidation of Primary Alcohols Catalyzed by Whole Cells from Rhodococcus erythropolis (E.C. 1.X.X.X) [29, 20, 31]*

(*R*)-Isopropylideneglycerol is a useful C_3 synthon in the synthesis of (*S*)- β-blockers, e.g., (*S*)-metoprolol. (*R*)-Isopropylideneglyceric acid can also be used as starting material for the synthesis of biologically active products. The resolution is carried out by selective microbial oxidation of the *S* enantiomer (Fig. 10). The chemical synthesis of (*R*)-isopropylideneglycerol starts from nonnatural L-mannitol or from L-ascorbic acid (Fig. 11). In comparison to the biotransformation, here a stoichiometric quantity of lead tetraacetate is needed.

Figure 10. Synthesis of (*R*)-isopropylideneglycerol and (*R*)-isopropylideneglyceric acid (International Biosynthetics)

1: isopropylideneglycerol, **2**: (*R*)-isopropylideneglyceric acid, **E**: oxidase (whole cells from *Rhodococcus erythropolis*).

Figure 11. Chemical synthesis of (*R*)-isopropylideneglycerol from nonnatural L-mannitol or from L-ascorbic acid

2.2.3. *Hydroxylation of Nicotinic Acid (Niacin) Catalyzed by Whole Cells of Achromobacter xylosoxidans (E.C. 1.5.1.13) [32-34]*

6-Hydroxynicotinate is a versatile building block, chiefly in the synthesis of modern insecticides. The 6-hydroxynicotinate-producing strain (Fig. 12) was found by accident when precipitated white crystals of 6-hydroxynicotinate were found in the mother liquor of a niacin-producing chemical plant. The second enzyme of the nicotinic acid pathway, decarboxylating 6-hydroxynicotinate hydroxylase, is strongly inhibited at niacin concentrations above 1 %, whereas niacin hydroxylase is unaffected. In contrast to the biotransformation the chemical synthesis of 6-substituted nicotinic acids is difficult and expensive due to the separation of byproducts that are produced by nonregioselective hydroxylations.

Figure 12. Synthesis of 6-hydroxynicotinate (Lonza)

1: niacin = nicotinic acid = pyridine-3-carboxylate, **2**: 6-hydroxynicotinate = 6-hydroxypyridine-3-carboxylate, **E**: nicotinic acid hydroxylase (whole cells of *Achromobacter xylosoxidans*).

2.2.4. *Reduction of Hydrogen Peroxide Concentration by Catalase (E.C. 1.11.1.6) [35]*

During oxidative coupling of 1-nitrotoluene to give dinitrodibenzyl (DNDB) hydrogen peroxide is formed as a byproduct. It is not possible to decompose H_2O_2 by adding heavy-metal catalysts because only incomplete conversion is reached, and subsequent process steps with DNDB are problematic due to contamination with heavy-metal catalyst. The biotransformation is only used to decompose the undesired side product H_2O_2 (Fig. 13). The enzyme of choice is catalase derived from a microbial source, which has advantages over bovine catalase since the activity remains constant over a broad pH range from 6.0 to 9.0, temperatures up to 50 °C are tolerated, and salt concentrations up to 25 % do not affect the enzyme stability. The reaction is carried out in a cascade of three continuous stirred-tank reactors (Fig. 14). The H_2O_2 concentration is reduced from 7000 to < 200 ppm in the product solution. The third vessel is aerated with nitrogen to degas the product solution. The dinitrodibenzyl is used as a pharmaceutical intermediate.

Figure 13. Degradation of hydrogen peroxide (Novartis).

1: 1-nitrotoluene, 2: dinitrodibenzyl (DNDB), E: catalase from a microbial source.

Figure 14. Flow scheme of dinitrodibenyl synthesis

2.2.5. *Bioconversion of N-Butylglucamine with Whole Cells of Gluconobacter oxydans (E.C. 1.1.99.21) [36]*

N-Butyldeoxynojirimycin is an inhibitor of glycosidase activity. A precursor for this potential therapeutic agent against retroviral infections, 6-deoxy-6-butylaminosorbose, is synthesized by oxidation with whole cells of *Gluconobacter oxydans* (Fig. 15). The enzyme involved is sorbitol dehydrogenase (SDH, see Section Alcohol Oxidation with Whole Cells of *Gluconobacter suboxydans* (E.C. 1.1.99.21)). The key to this process is the temperature of the biotransformation, due to degradation of the sorbose product. The selectivity could be enhanced by lowering the process temperature to 12–15 °C, and the product was obtained in 95 % yield. With optimized conditions the process was scaled up to a 5500 L reactor.

Figure 15. Biosynthesis of 6-deoxy-6-butylaminosorbose (Pharmacia)

1: *N*-butylglucamine, **2**: 6-deoxy-6-butylaminosorbose, **E**: whole cells of *Gluconobacter oxydans*.

2.3. Hydrolytic Cleavage and Formation of C—O and C—N Bonds by Hydrolases (E.C. 3)

2.3.1. *Kinetic Resolution of a Diester by Protease Subtilisin Carlsberg from Bacillus sp. (E.C. 3.4.21.62) [37], [38]*

(*R*)-(2-Methylpropyl)butanedioic acid 4-ethyl ester is used as chiral building block for potential collagenase inhibitors (e.g., Ro 31-9790) for the treatment of osteoarthritis. A 20 % emulsion of the diester in 30 mM aqueous $NaHCO_3$ is treated with Protease L660 or Alcalase 2.5L (9 % with respect to the racemic diester; Fig. 16). The unconverted *S* diester can be extracted into a solvent such as toluene and racemized by heating the anhydrous extract with catalytic amounts of sodium ethanolate. The resulting racemic diester can be recycled, and thus the overall yield is improved from 45 to 87 %. The reaction was repeatedly carried out on a 200 kg scale with respect to the racemic diester. The enzyme is highly stereoselective even at high substrate concentrations (20 %). The chemoenzymatic route starting from the cheap bulk agents maleic anhydride and isobutylene replaced the existing chemical synthesis for bulk amounts (Fig. 17).

Figure 16. Synthesis of (*R*)-(2-methylpropyl)butanedioic acid 4-ethyl ester (Hoffmann La-Roche)

1: (*R*)-(2-Methylpropyl)butanedioic acid diethyl ester, **2**: (*R*)-(2-methylpropyl)butanedioic acid 4-ethyl ester, Na form, **E**: hydrolase (subtilisin Carlsberg from *Bacillus sp.*).

Figure 17. Comparison of drug discovery and process research route to Ro 31-9790

2.3.2. *Kinetic Resolution of α-Amino Acid Amides Catalyzed by Aminopeptidase from Pseudomonas putida (E.C. 3.4.1.11) [39-42]*

Enantiomerically pure α-amino acids are intermediates in the synthesis of antibiotics and are used for parenteral nutrition and as food and feed additives (⟶ Amino Acids). Examples are D-phenylglycine and 4-hydroxyphenylalanine for semisynthetic β-lactam antibiotics and L-phenylalanine for the peptidic sweetener aspartame. DSM also used this process to produce L-homophenylalanine, a potential precursor for several ACE inhibitors.

The α-amino amides as substrates for this enantiospecific, biocatalytic amide hydrolysis can be readily obtained from the appropriate aldehydes by Strecker synthesis (Fig. 18). As whole-cell catalyst *Pseudomonas putida* is applied, which accepts a wide range of substrates. Subsequent to the biotransformation benzaldehyde is added to precipitate the D-

amide Schiff base, which can be easily isolated by filtration. An acidification step leads to the D-amino acid. The L-amino acid can be reused after racemization, so that a theoretical yield of 100 % D-amino acid is possible. The same process can be used for the synthesis of 100 % L-amino acids by racemizing the Schiff base of the D-amide with small amounts of base in organic solvents.

Figure 18. Production of L- and D- α-amino acids by kinetic resolution of α-amino acid amides (DSM)

1: aldehyde, **2**: aminonitrile, **3**: α-amino acid amide, **4**: α-amino acid methyl ester, **5**: α-amino acid, **6**: α-amino acid amide, **7**: Schiff base of α-amino acid amide, **E**: aminopeptidase from *Pseudomonas putida*.

By using in vivo protein engineering not only mutant strains of *Pseudomonas putida* exhibiting L-amidase and D-amidase, but also amino acid amide racemase activities were obtained. Using these mutants a convenient synthesis of α-amino acids with 100 % yield would be possible with a one-cell system. It is noteworthy that only α-H substrates can be used. By screening, a new biocatalyst of the strain *Mycobacterium neoaurum* was found which is capable of converting α-substituted amino acid amides.

2.3.3. *Production of L-Methionine by Kinetic Resolution with Aminoacylase of Aspergillus oryzae (E.C. 3.5.1.14) [43-46]*

The *N*-acetyl-D,L-amino acid precursors are conveniently accessible through acetylation of D,L-amino acids with acetyl chloride or acetic anhydride in a Schotten–Baumann reaction or by amidocarbonylation [47]. For the acylase reaction Co^{2+} is added as metal effector to yield an increased operational stability of the enzyme (Fig. 19). The unconverted acetyl-D-methionine is racemized by acetic anhydride in alkali, and the racemic *N*-acetyl-D,L-methionine is reused. The racemization can also be carried out in a molten bath or by an acetyl amino acid racemase. The L-methionine product is recovered by crystallization, because L-methionine is much less soluble than the acetyl substrate. The production is carried out in a continuous stirred-tank reactor. A polyamide ultrafiltration membrane with a cutoff of 10 000 dalton retains the enzyme and thus decouples the residence times of catalyst and reactants. L-Methionine is produced with an e.e. > 99.5 % and a yield of 80 % with a capacity of > 300 t/a. Degussa produces several proteinogenic and nonproteinogenic amino acids in the same way, e.g., L-alanine, L-phenylalanine, α-aminobutyric acid, L-valine, L-norvaline, and L-homophenylalanine.

Figure 19. Biocatalytic production of L-methionine by kinetic resolution (Degussa)

1: *N*-acetyl-D,L-methionine, **2**: *N*-acetyl-D-methionine, **3**: L-methionine, **4**: acetic acid, **E**: aminoacylase from *Aspergillus oryzae*.

2.3.4. *Synthesis of β-Lactam Antibiotics Catalyzed by Penicillin Acylase (E.C. 3.5.1.11) [48-51]*

The penicillin acylases do not accept charged amino groups. Therefore phenylglycine itself cannot be used at a pH value at which the carboxyl function is necessarily uncharged, because the amino group will then be charged. To reach nonequilibrium concentrations of the product, the substrate must be activated as an ester or amide (Fig. 20). Thus the amino group can be partly uncharged at the optimal pH value of the enzyme. In biological systems ATP delivers the activation energy. Using the same synthetic pathway, alternatively to 7-ADCA and 7-ACCA also 6-APA derivatives can be synthesized.

Figure 20. Synthesis of β-lactam antibiotics (Chemferm)

1a: phenylglycine amide (PGA; R^1 = H, R^2 = NH_2), **1b**: phenylglycine methyl ester (PGM; R^1 = H, R^2 = OMe), **1c**: hydroxyphenylglycine amide (HPGA; R^1 = OH, R^2 = NH_2), **1d**: hydroxyphenylglycine methyl ester (HPGM; R^1 = OH, R^2 = OMe), **2a**: 7-aminodeacetoxy-3-methylcephalosporanic acid (7-ADCA; R^3 = Me), **2b**: 7-aminodeacetoxy-3-chlorocephalosporanic acid (7-ACCA; R^3 = Cl), **3a**: Cefaclor (R^1 = H, R^3 = Cl), **3b**: Cephalexin (R^1 = H, R^3 = Me), **3c**: Cefadroxil (R^1 = OH, R^3 = Me).

The established chemical synthesis started from benzaldehyde and included fermentation of penicillin (Fig. 21). The process consists of ten steps and produces 30–40 kg of waste per kilogram product. The waste contained methylene chloride, other solvents, silylating agents, and numerous products from side-chain protection and acylating promoters. In comparison the chemoenzymatic route needs only six steps, of which three are biocatalytic. The biotransformation **E1** in Figure 21 is carried out with penicillin amidase from *Escherichia coli* (E.C. 3.5.1.11), and **E2** with aminopeptidase from *Pseudomonas putida* (E.C. 3.4.1.11).

Figure 21. Comparison of chemical and biocatalytic synthesis of cefalaxin

E1: penicillin amidase, **E2**: amino peptidase, **E3**: penicillin acylase.

7-ADCA = 7-aminodeacetoxy-3-methylcephalosporanic acid (see Fig. 20).

2.3.5. *Enantioselective Synthesis of an Aspartame Precursor with Thermolysin from Bacillus proteolicus (E.C. 3.4.24.27) [52], [53]*

Since the reaction (Fig. 22) is limited by equilibrium the products must be removed from the reaction mixture to reach high yields. Therefore, an excess of racemic phenylalanine methyl ester, which is inert to the reaction, is added. The carboxylic anion of the protected aspartame forms a poorly soluble adduct D-Phe-OCH_3, which precipitates from the reaction mixture and can be removed easily by filtration. The final steps of the process are the separation of D-Phe ester, removal of protecting groups, and racemization of the formed L-amino acid. α-Aspartame is produced with > 99.9 % e.e. World capacity is about 10 000 t/a, of which about 2500 t/a is produced by enzymatic coupling. Since the bacterial strain was found in the Rokko Hot Spring in central Japan it is thermally stable (up to 60 °C).

Figure 22. Biocatalytic synthesis of aspartame (Holland Sweetener Company)

1: phenylalanine methyl ester, **2**: aspartic acid (protected), **3**: α-aspartame (protected), thermolysin from *Bacillus proteolicus*.

The main problem in chemical synthesis by coupling of Z-Asp anhydride with L-Phe-OCH_3 is the formation of β-aspartame as byproduct. This isomer has a bitter taste and must be completely removed from the α isomer. The advantages of the enzymatic route are:

1. no β isomer is produced,
2. the enzyme is completely stereoselective, so that racemic mixtures of the substrate or the appropiate enantiomer of the amino acid can be used,
3. no racemization occurs during synthesis, and
4. the reaction takes place in aqueous media under mild conditions.

2.3.6. *Hydrolysis of Heterocyclic Nitriles by Nitrilase/Hydroxylase from Agrobacterium sp. (E.C. 3.5.5.1) [54-56]*

5-Hydroxypyrazine-2-carboxylic acid (Fig. 23) is a versatile building block in the synthesis of new antituberculosis agents, e.g., 5-chloropyrazine-2-carboxylic acid esters. The regioselective hydroxylation of pyrazine-2-carboxylic acid is catalyzed by a hydroxylase (**E2**, E.C. 1.5.1.13), which is contained in suspended whole cells of *Agrobacterium sp*. The biomass is separated by ultrafiltration (cutoff 10 kDa) after biotransformation. 5-Hydroxypyrazine-2-carboxylic acid is precipitated from the permeate by acidification with sulfuric acid to pH 2.5.

Figure 23. Biocatalytic synthesis of 5-hydroxypyrazine-2-carboxylic acid (Lonza)

1: 2-cyanopyrazine, **2**: pyrazine-2-carboxylic acid, **3**: 5-hydroxypyrazine-2-carboxylic acid, **E1/E2**: nitrilase/hydroxylase (whole cells of *Agrobacterium sp*., which contains both enzymes.

In contrast to the biotransformation the chemical synthesis of 5-substituted pyrazine-2-carboxylic acid leads to a mixture of 5- and 6-substituted pyrazinecarboxylic acids and requires multiple steps.

2.3.7. *Resolution of 3,3,3-Trifluoro-2-hydroxy-2-methylpropionamide with Amidase from Klebsiella oxytoca (E.C. 3.5.X.X) [57]*

A novel heat-stable amidase from *Klebsiella oxytoca* has been isolated, characterized, and cloned. For safety reasons, the amidase is overexpressed in *E. coli*. As homogeneous biocatalyst heat-treated whole cells of *E. coli* are used for the hydrolysis the methylpropionamide to give the *R* acid and the *S* amide. The amide can be hydrolyzed chemically to the *S* acid, which could be obtained as product as well (Fig. 24). Optical purity is greater than 98 % for the acid, which is produced on a 100 kg scale. The products are intermediates for the synthesis of a number of potential pharmaceuticals, which include ATP-sensitive potassium channel openers and diabetes remedies.

Figure 24. Resolution of 3,3,3-trifluoro-2-hydroxy-2-methylpropionamide (Lonza)

1: 3,3,3-trifluoro-2-hydroxy-2-methylpropionamide, **2**: 3,3,3-trifluoro-2-hydroxy-2-methylpropionic acid, **E**: amidase from

Klebsiella oxytoca.

2.4. Formation of C—C, C—O, and C—N Bonds by Lyases (E.C. 4)

2.4.1. *Hydrocyanation of m-Phenoxybenzaldehyde with Oxynitrilase from Hevea brasiliensis (E.C. 4.1.2.39) [58]*

Whole cells of an undisclosed host microorganism overproducing the oxynitrilase from *Hevea brasiliensis* are used in a biphasic solvent system of aqueous buffer and methyl *tert*-butyl ether for the enantioselective hydrocyanation of *m*-phenoxybenzaldehyde (Fig. 25). This biphasic system has been proven beneficial and applicable on an industrial scale. The product is an important precursor for pyrethroids.

Figure 25. Hydrocyanation of *m*-phenoxybenzaldehyde (DSM)

1: *m*-phenoxybenzaldehyde, **2**: (*S*)-*m*-phenoxybenzaldehyde cyanohydrin, **E**: (*S*)-oxynitrilase from *Hevea brasiliensis*.

2.4.2. *Synthesis of Carnitine Catalyzed by Carnitine Dehydratase in Whole Cells (E.C. 4.2.1.89) [59-61]*

L-Carnitine is used in infant, health, sport, and geriatric nutrition. The biotransformation is catalyzed by carnitine dehydratase in whole cells (Fig. 26). (*R*)-Carnitine is produced with > 99.5 % conversion of 4-butyrobetaine and > 99.5 % e.e.. The mutant strain has blocked L-carnitine dehydrogenase and excretes the accumulated product. The purified enzyme could not be used for the biotransformation due to its high instability. Apart from usual batch fermentations, continuous production is also feasible since the cells go into a “maintenance state” with high metabolic activity and low growth rate. The cells can be recycled after separation from the fermentation broth by filtration. A chemical resolution process with L-tartaric acid that was developed at Lonza was no longer competitive to the biotechnological route. A more attractive route would be the Ru/BINAP-catalyzed asymmetric hydrogenation of 4-chloroacetoacetate (Fig. 26), in which an e.e. of 97 % is achieved.

Figure 26. Comparison of chemical and biocatalytic syntheses of carnitine (Lonza)

1: 4-butyrobetaine, **2**: carnitine, **E**: carnitine dehydratase in whole cells of *E coli*.

2.4.3. *Synthesis of L-Dopa Catalyzed by Tyrosine Phenol Lyase from Erwinia herbicola (E.C. 4.1.99.2) [62-65]*

L-Dopa is used for the treatment of Parkinsonism that is caused by a lack of L-dopamine and its receptors in the brain. L-Dopamine is synthesized in organisms by decarboxylation of L-3,4-dihydroxyphenylalanine (L-dopa). Since L-dopamine can not pass the blood–brain barrier L-dopa is applied in combination with dopadecarboxylase inhibitors to avoid formation of L-dopamine outside the brain. Ajinomoto produces L-dopa by this lyase biotransformation (Fig. 27) with suspended whole cells in a fed batch reactor on a scale of 250 t/a. Much earlier Monsanto has successfully scaled up the chemical synthesis of L-dopa (Fig. 28).

Figure 27. Biocatalytic synthesis of L-dopa (Ajinomoto)

1: catechol, **2**: pyruvic acid, **3**: L-dopa, **E**: tyrosine phenol lyase from *Erwinia herbicola*.

Figure 28. Chemical synthesis of L-dopa (Monsanto)

1: vanillin, **2**: azlactone, **3**: (*Z*)-enamide, **3**: L-dopa.

The enantioselective hydrogenation of 3,4-dihydroxy-*N*-acetylamino cinnamic acid is catalyzed by a cationic Rh complex of the biphosphine DIPAMP, in which the enantioselectivity is introduced by the chiral phosphine [66], [67]. The hydrogenation proceeds quantitatively with 94 % e.e.. The optically pure L-dopa is separated from the catalyst by crystallization.

2.4.4. *Synthesis of Nicotinamide Catalyzed by Nitrile Hydratase from Rhodococcus erythropolis (E.C. 4.2.1.84) [34], [68]*

Nicotinamide (vitamin B3) is used as vitamin supplement for food and animal feed. The same strain is used as in the industrial production of acrylamide [3]. The biotransformation is carried out on a scale of 3000 t/a (Fig. 29).

Figure 29. Comparison of chemical and biocatalytic syntheses of nicotinamide (Lonza)

E: nitrile hydratase (whole cells of *Rhodococcus erythropolis*).

In contrast to the chemical alkaline hydrolysis of 3-cyanopyridine with 4 % of nicotinic acid byproduct (96 % yield) the biotransformation gives complete selectivity and no acid or base is required. The continuous biotransformation is operated at low temperature and atmospheric pressure. In contrast to the old synthesis route for nicotinamide at Lonza the new pathway is environmentally friendly and safe. Only one organic solvent is used throughout the whole process in four highly selective, continuous, and catalytic reactions. The process water, NH_3, and H_2 are recycled.

2.4.5. *Synthesis of Mandelic Acid with Nitrilase (E.C. 4.2.1.84) [5], [69]*

By kinetic resolution of racemic mandelonitrile (Fig. 30) mandelic acid is produced on a multiton per year scale. By choosing the appropriate reaction conditions (i.e., pH) the remaining enantiomer in the resolution is re-racemized in the presence of cyanide ions due to an equilibrium between hydroxy nitrile and aldehyde.

Figure 30. Resolution of mandelonitrile (BASF)

1: mandelonitrile, **2**: mandelic acid, **E**: nitrilase.

2.5. Epimerization of Glucosamine Catalysed by Epimerase from *E. coli* (E.C. 5.1.3.8) [70, 71]

N-Acetyl-D-mannosamine serves as *in situ* generated substrate for the synthesis of *N*-acetylneuraminic acid. Since *N*-acetyl-D-mannosamine is quite expensive it is synthesized from *N*-acetyl-D-glucosamine by epimerization at C-2. This biotransformation is integrated in the production of *N*-acetylneuraminic acid (Neu5Ac).

By using *N*-acylglucosamine 2-epimerase it is possible to start with the inexpensive *N*-acetyl-D-glucosamine instead of *N*-acetyl-D-mannosamine (Fig. 31). The epimerase is used for the *in situ* synthesis of *N*-acetyl-D-mannosamine (ManNAc). Since the equilibrium is on the side of the starting material, the reaction is driven by the subsequent biotransformation of ManNAc together with pyruvate to give Neu5Ac.

Figure 31. Biocalytic epimerization of glucosamine to mannosamine (Marukin Shoyu)

1: *N*-acetyl-D-glucosamine, **2**: *N*-acetyl-D-mannosamine, **E**: *N*-acylglucosamine 2-epimerase from *E. coli*.

The *N*-acylglucosamine 2-epimerase is cloned from porcine kidney, transformed and overexpressed in *Escherichia coli*. To reach maximal activity ATP and Mg^{2+} must be added. Since the whole synthesis is reversible high GlcNAc concentrations are used.

The chemical epimerization of GlcNAc is carried out by Glaxo. The equilibrium of the chemical epimerization is on the side of *N*-acetyl-D-glucosamine (GlcNAc:ManNAc = 4:1). After neutralization and addition of 2-propanol GlcNAc precipitates. In the remaining solution a ratio of GlcNAc:ManNAc = 1:1 is reached. After evaporation to dryness and and extraction with methanol the GlcNAc:ManNAc ratio is shifted to 1:4.

[Top of Page]

3. Outlook

Biotransformations have gained more and more importance in industry. Classical chemical steps in the industrial synthesis have been successfully replaced. For industrial application biocatalysts need not be immobilized. Moreover the potential of biocatalysis is still increasing. By improved screening methods new catalysts will be detected and made available in large amounts by cloning and overexpression. Directed evolution will be used to improve properties such as stability or selectivity [73], [74]. Metabolic engineering will be used to analyze and remove bottlenecks in the metabolism or to create novel biocatalysts [75].

1. Properties

Pure sodium cyanide NaCN [*143-33-9*] and potassium cyanide KCN [*151-50-8*] are white crystalline solids. They are readily soluble in water and can be dissolved to prepare aqueous solutions with ca. 30 % (NaCN) and ca. 40 % (KCN) concentration at 20 °C. These cyanides are often called "alkaline cyanides" because they render water alkaline pH when dissolved. This is due to a dissolution equilibrium in which free alkali is formed from these salts of a weak acid and a strong base:

$$MCN + H_2O \rightleftarrows HCN + MOH$$

Apart from dissolution in water, HCN can be formed and released from alkali metal cyanide solutions and solids by contact with a large range of weak to strong acids. The liberation of HCN is pH-dependent (Fig. 1).

On contact with acids the white color of solid cyanides can change, and colorless solutions can turn light yellow to dark brown. The intensity of the color change

Figure 1. HCN/cyanide equilibrium versus pH

depends on a variety of parameters. This behavior is due to polymerization of HCN under alkaline conditions. As this behavior is of importance for the quality of cyanide solutions, these products must be stabilized by addition of excess alkali. The alkali (normally NaOH or KOH) acts as a pH buffer whenever cyanide comes into contact with smaller amounts of acids and neutral-

10.1002/14356007.i01_i01

izes them. In this sense alkali metal cyanides are sensitive to any contact with humid air which contains carbon dioxide, which is a weak acid in aqueous solution. Only when additional stabilization with alkali has been carried out is the acid neutralized to form carbonate and the cyanide protected from decomposition by the acid.

Further physical properties of NaCN and KCN are listed in Table 1.

Table 1. Physical properties of NaCN and KCN

Physical quantity	NaCN	KCN
M_r, relative molecular mass	49.015	65.119
mp, melting point	561.7 °C (98 wt %)	634.5 °C (98 wt %)
bp, boiling point	1500 ± 10 °C	
ϱ, density	1.620 g/cm^3 (6 °C, rhombic) 1.595 g/cm^3 (20 °C, cubic) 1.19 g/cm^3 (850 °C, fused)	1.553 g/cm^3 (20 °C, cubic) 1.56 g/cm^3 (25 °C, cubic)
c_p, specific heat capacity	1.667 kJ kg^{-1} K^{-1} (273.1 K) 17.950 kJ kg^{-1} K^{-1} (288.0 K) 1.402 kJ kg^{-1} K^{-1} (298.6 K)	1.00 kJ kg^{-1} K^{-1} (25 – 72 °C)
H, enthalpy (25 °C)	−89.9 kJ/mol	−112.63 kJ/mol
ΔH_f, heat of fusion	314 kJ/kg	225 kJ/kg
ΔH_v, heat of vaporization	3185 kJ/kg	
p_v, vapor pressure	0.10 kPa (800 °C) 1.65 kPa (1000 °C) 11.98 kPa (1200 °C) 39.10 kPa (1350 °C)	
Solubility in 100 g of		
Ethanol, 100 %	1.235 g (25 °C)	0.57 g (19.5 °C)
Ethanol, 95 %	2.445 g (25 °C)	
Methanol	6.44 g (15 °C) 4.58 g (25 °C) 4.10 g (67.4 °C)	4.91 g (19.5 °C)
NH_3, liquid	58 g (−31 °C)	4.55 g (−33.9 °C)

2. Production, Packaging, and Transport

Sodium and potassium cyanide are produced in the same way in Europe and worldwide: gaseous or liquid HCN reacts with a solution of sodium or potassium hydroxide. The formation of cyanides is chemically a simple neutralization reaction between a weak acid (HCN) and a strong base (OH^-). The neutralization reaction has an energy release of 460 kJ/mol, which leads to additional heating of the reaction solution and saves energy.

The efficiency of the neutralization reaction is very high, and the yield based on HCN is close to 100 %. Thus all of the HCN used is transferred into the end products NaCN or KCN, and only minimal losses of HCN occur.

The reaction results in the formation of a dissolved salt. The raw solution can either be concentrated or diluted with water, depending on what kind of intermediate product form is produced. Normally, the aim is to form a concentrated solution with ca. 30 % cyanide. Commercial solid sodium and potassium cyanide can be crystallized by evaporation of excess water.

Worldwide most alkali metal cyanides are produced by utilizing HCN as cyanide source. The production of HCN (→ Cyano Compounds, Inorganic, Chap. 1.2) is, therefore, an important intermediate step for the production of alkali cyanides.

Andrussow process for HCN production:

$$CH_4 + NH_3 + 1.5O_2 \rightarrow HCN + 3H_2O \quad \Delta H = -474\,kJ/mol$$

BMA process for HCN production:

$$CH_4 + NH_3 \rightarrow HCN + 3H_2 \qquad \Delta H = +252\,kJ/mol$$

In the production of acrylonitrile:

$$2\,C_3H_6 + 2\,NH_3 + 3\,O_2 \rightarrow 2\,CH_2CHCN + 6\,H_2O$$

HCN is formed as a byproduct:

$$C_3H_6 + 2\,NH_3 + 8\,O_2 \rightarrow 2\,HCN + 8\,H_2O + 4\,CO_2$$

There are patented cyanide production processes available which directly form solid material in a fluidized-bed reactor using an alkali solution and HCN gas as raw materials. Also processes are patented that use a cyanide solution as the cyanide source, and solid cyanide is produced by a drying process in a fluidized-bed reactor.

2.1. Classical Cyanide Production Processes

The following processes are termed classical as they are not applied to any significant extent in Europe presently but were used in earlier cyanide production.

In the *Castner – Keller process* sodium metal reacts with charcoal and ammonia at around 600 °C in a melt:

$$Na + C + NH_3 \rightarrow NaCN + 3/2\ H_2$$

This process was mainly developed by Degussa and applied there until 1971.

The *calcium cyanamide process* is very similar to the Castner process, but uses calcium carbonate as the carbon source for the cyanide ion.

In the *"blood process"* potassium or sodium carbonate was fused with potassium hexacyanoferrate(II), for which mainly animal blood and wastes were used as raw materials.

2.2. Cyanide Production Processes

Cyanides are made by melt processes or by processes in aqueous solution using HCN as the cyanide source. Most cyanide is produced nowadays using solution processes. Only where (electrical) energy costs are sufficiently low can melt processes be competitive.

Melt processes do not apply any cyanide sources as raw materials, but produce the cyanides from non-cyanide components. The result of the processes is a solid cyanide with different kinds of impurities, e.g., carbon black from using carbon as raw material.

Cyanides can be produced in batch and in continuous operation. Liquid cyanide solutions are easily pumped as the viscosity is moderate even at the highest achievable concentration.

Figure 2 shows a flow sheet for NaCN production.

Production of Cyanide Solution. The production of the cyanide solution (NaCN, KCN) is the basic first production step. Further processing of the resulting raw cyanide solution usually consists of concentration of the solution by evaporation of excess water, cooling, filtering, and storage. The exact ratios of cyanide in water are strongly dependent on the water balance. When a concentrated NaOH solution (50 %) and pure HCN (99 %) are used a cyanide solution with ca. 46 % sodium cyanide is formed which needs to be further diluted with water to give a commercial product.

Figure 2. Example of a solid cyanide production plant

Solutions are often directly used in cases where the site of industrial application is close enough to the cyanide production site to keep the transport of solution competitive (energy for evaporation of the excess water, formulation of the solid material). This is, therefore, usually only applied if the application site can directly use a concentrated cyanide solution (30 wt %). This is, for example, the case for gold mining operations in Nevada, South Africa, and Australia. Cyanide solution is normally shipped in tank trucks to the gold mine, subsequently stored in liquid tanks at the site, and diluted for further use, if necessary.

Many gold mines are too far away from the raw material production site to be supplied with liquid material and, therefore, need solid NaCN.

Cyanide solutions normally contain approx. 24 – 30 % NaCN. Cyanide solutions transported at cold times of the year or in cold regions may contain lower cyanide concentrations to prevent crystallization during transport and storage in unheated devices.

In cases where an application requires HCN as a liquid or a gas and no HCN production is available on site, cyanide solutions or solids can be used as the source. They need only be acidified, and the HCN is distilled and taken to production. Normally, it is not stored intermediately.

Production of Solid Cyanides. Solid cyanide is made from solution by crystallization of solid cyanides from the liquid, separation of the wet solid with further drying and mechanical handling to form stable solid product forms. Figure 3 shows a plant for the production of solid cyanides. The preferred solid forms are bricks, granules, tablets, and powder. Bricks are made by compacting of the wet filter cake with subsequent drying and also by first drying the crystals followed by compacting. Bricks are also made from granules. Powder can be made by grinding and subsequent sieving of fines material.

Figure 3. Flow chart of the main production steps for cyanide production (NaCN as example)

The cyanide content in solids is usually very high and specified for normal applications in a range of higher than 98 % and even higher than 99 %.

2.3. Energy Consumption

The energy costs for cyanide production are mainly due to electricity and steam and correspond to approx. 1.3 – 1.5 t of steam per ton of solid 100 % NaCN or KCN.

2.4. Packaging and Transport [5, 6]

Production includes packaging of cyanides for the safe storage and transport. Normally cyanides are filled into metal drums holding between 50 and 100 kg or 1 t big bags which are transported in wooden boxes. All packaging must have UN registration for the packaging of hazardous materials. Returnable packaging for multiple use is an important alternative to the use of one-way packaging. Both one-way packaging and returnable packaging for solid material are used worldwide. Another alternative for transport is the so-called solid to liquid system (SLS). Here, solid cyanides are filled into a unit containing approx. 20 t of material. This unit is transported to the customer's site and the cyanide is dissolved directly at the user's facility and pumped to a storage tank. The transportation unit can be reused and refilled with solid material many times. The preferred type of packaging often depends on the specific transport conditions, which are due to technical, economical, and environmental considerations.

Figure 4 shows storage of solid cyanide in drums.

Transport is regulated by national and international regulations and laws. Road transport of liquid cyanides is allowed in various European countries. However liquid cyanide is preferably shipped by rail cars within Europe. Only certified companies with a special permit for the transportation of dangerous goods are approved. Some European countries require special permits for the transport of cyanides on the road, e.g., Italy. Each transport in Europe is also required to have a transport emergency card with relevant information on cyanide on board.

Figure 4. Storage facility for solid cyanide in drums

In Germany, it is allowed to ship cyanides and acids together in the same shipment (trucks). But for safety reasons cyanides and acids should not be transported and stored together.

Transportation of cyanide solution is mostly favored in cases where transport routes to the end-users are considered to be safe and the distance short enough that transport of liquid products is economic compared to the alternative of solid cyanide. Also the customer must be in the position to directly use the solution.

Production of solid material from cyanide solutions is mostly the best alternative when the product is transported over long distances, when the transport of liquid is not allowed according to national regulations, and when the customers are prepared to store and use solid material.

2.5. Responsible Care, Product Stewardship, Sustainable Development, Certification [7–19]

Production facilities can be certified according to international standards referring to product and management system quality including the relevant aspects of (workers') health, safety, and environmental management or any other systems that lead to similar results. This includes certification according to ISO 9001, 14001, or any other management system that is applicable to manage company and stakeholder needs sufficiently.

Cyanide producers who supply cyanide to gold mines are increasingly being asked to fulfill the requirements of the cyanide producers verification audit protocol according to the International Cyanide Management Code (ICMC) provisions. The overall basis for this kind of certification is the International Cyanide Management Code for the gold mining industry.

All cyanide producers supply material safety data sheets (MSDS) to their customers covering all specific information needed for the safe handling and use of their products. Information and training programmes are in place for traders, end-users, and transport companies.

Transport route analysis from the production facility to the sites of the end-users (mainly for the mining industry) are carried out by producers.

Major European cyanide producers exchange information on safety, health, and environmental aspects of their products an a regular basis within the CEFIC Cyanide Sector Group. This group has, for example, developed a Mutual Aid Scheme (MAS) for transportation incidents with cyanides and published the "Guidelines for Storage, Handling, and Distribution of Alkali Cyanides".

3. Emissions and Consumptions [20–26]

Hazardous Emissions from cyanide production can be emissions of HCN and NH_3 gases and of cyanides, the last-named mainly in wastewater or as particles in the workplace.

NH_3 and HCN can be detected by humans due to their specific odor at low detection limits. These limits are far below any workplace limits. Therefore, people may be warned even without any technical monitoring devices. However, a significant number of persons are not able to detect HCN, and a much smaller number can not detect NH_3 by its smell. Hence, in accordance with standard workplace regulations, monitoring devices must be installed, mainly for the detection of HCN and also for NH_3.

The production of cyanide solutions is operated under closed conditions where no HCN can leak from the units. As a result the overall emission of HCN from cyanide production plants in Europe and elsewhere are below the European and national regulation limits (e.g.,TA Luft in Germany) and below 10 kg HCN per year for a 20 000 t/a production facility.

NH_3 emissions may result from heating cyanides and cyanide solutions. NH_3 formation from cyanide production can result from the hydrolysis of cyanides at higher temperature, which can result in the formation of cyanate. The formation and the subsequent emission of NH_3 to the environment is very low and below reportable limits, i.e., less than 15 kg NH_3 per year.

Detoxification of Cyanides. The detoxification of cyanides can be carried out by using different kinds of oxidizing agents, such as hypochlorite or peroxides. Pure oxygen is not suitable. Using hypochlorite creates a significant salt load of the effluent and can create additional contributions to AOX load. Using H_2O_2 based technology does not create any of these byproducts and can be seen as the best choice for cyanide detoxification at a cyanide production plant.

$$NaCN + OCl^- \rightarrow OCN^- + NaCl$$

$$CN^- + H_2O_2 \rightarrow OCN^- + H_2O$$

Cyanide which is dissolved in process wastewater can be treated by the above-mentioned methods, but preferably peroxides are used (Fig. 5).

Wastewater. The process solution can directly be fed to a biological treatment plant under predefined conditions. Also diluted cyanide effluent streams may directly be added to a biological wastewater treatment, where bacteria break down the cyanide to nontoxic substances and use the chemical as feed.

As a result of detoxification the free cyanide in the treated water is far below 0.01 ppm. The total amount of cyanide transferred to the environment from a 20 000 t/a NaCN plant normally is below 50 kg/a. These small cyanide emissions which enter, e.g., rivers at a very low concentration do not pose harm to fish and the environment and are much likely also detoxified further by microorganisms.

Excess water from concentrating cyanide solutions is evaporated and either recycled to the process water after condensation or detoxified as mentioned above. No contaminated water is emitted to the air.

While most of the evaporated water is subsequently condensed, a small amount of the vapors

Figure 5. Detoxification facility for cyanides in a production plant

and noncondensables must be treated before release to the atmosphere. This is accomplished through the use of wet scrubbers, incineration, or a combination of both. Wet scrubber systems utilize liquid scrubbing solutions designed to contain or neutralize the noncondensable gases. Destruction efficiencies for these systems exceed 98 %. Incineration or thermal oxidation systems are also utilized for detoxification of the gasses. Destruction efficiencies for these systems exceed 99 %.

4. Quality Specifications, Impurities

The main impurities arising during the production of cyanides are cyanate (OCN^-), formate ($HCOO^-$), and carbonate (CO_3^{2-}). However, generally speaking, none of these are critical in any way for the applications in gold mining, the chemical industry, and electroplating. Very often these impurities are formed in application processes anyway.

Carbonates originate mainly from contact of excess alkali in the cyanide solution with atmospheric carbon dioxide. Hydrolysis of cyanide at higher temperatures (e.g., in drying sections, in hot solutions) leads to an increased content of formate, and ammonia is also formed. Cyanate can be formed by oxidation.

Ammonia can also occur as a possible impurity, especially in solutions after longer storage at elevated temperatures. If slow hydrolysis in solid (wet) material takes place, the ammonia formed can be released to the gas phase.

Due to reactions that lead to the formation of HCN and/or NH_3 commercial cyanide solutions can — mainly after prolonged storage under nonideal conditions — have a smell of HCN and/or NH_3. Absolutely dry cyanides normally do not smell of these species, as the presence of water is necessary for any of the decomposition reactions that lead to the release of HCN and/or NH_3.

For high-quality applications in the electroplating industry the content of a number of heavy metals is critical. Therefore, these must be below specified limits, which are, for example, defined in the DIN-ISO 50971. To achieve the DIN standards the respective alkali metal source (NaOH, KOH) must meet these requirements, as only these raw materials can act as sources of these metals. Due to its production processes, HCN is free of these metals.

For applications in high-quality electroplating and for most chemical synthesis applications, especially for the pharmaceutical industry, the specification for cyanides according to DIN-ISO 50971 can be regarded as a typical minimum quality requirement.

5. Uses

5.1. Gold Mining [27–32]

The majority of world sodium cyanide production is used in gold mining to extract gold from its ores (→ Gold, Gold Alloys, and Gold Compounds, Chap. 4.2). Elemental gold is very stable and does not react easily, even with very aggressive chemicals. Usually only in the presence of a strong oxidant together with a complexing agent can gold become water-soluble (formation of soluble gold salts). A classical example of how gold can be dissolved is the use of aqua regia, a mixture of the strong oxidant HNO_3 and the complexing agent HCl, where the chloride ion is the complexant for the gold. More weakly oxidizing conditions can be applied if a very strong complexing anion is used. In gold mining, cyanide is the complexing agent for the gold. Even by oxidation with oxygen (air, peroxides) under normal reaction conditions (dilute, slow reaction speed, moderate to low temperature) elemental gold is dissolved by oxidation and then subsequently complexed with cyanide:

$$4\,NaCN + 2\,Au + 1/2\,O_2 + H_2O \rightarrow 2\,Na\left[Au(CN)_2\right] + 2\,NaOH$$

While the gold chloride complex is unstable in dilute aqueous solution, even very low concentrations of the gold cyanide complex are stable in water over a wide pH range.

Cyanides are used in gold mining, although they are acutely toxic, mainly because of their high efficiency and selectivity, and they can not easily be substituted by other chemicals. In gold mining, not using cyanides would basically mean the termination of primary gold production. Only approx. 10 % of gold production today runs without the application of

cyanides. There have been numerous attempts to develop gold mining processes using alternative lixiviants for gold extraction. None of the alternative lixiviants or processes have ever been applied successfully in any large-scale operation on a worldwide basis. In this sense, only cyanide can fulfil the requirements of the gold mining industry to extract gold from the variety of ores in an economical and environmentally sound manner.

5.2. Chemical Synthesis

In a number of reactions, cyanides are used as starting materials or intermediates. Important examples in chemical synthesis are the cyanidation of acyl chlorides forming acyl cyanides as intermediate products:

$$RC(=O)Cl + NaCN \rightarrow RC(=O)CN + NaCl$$

and the nucleophilic substitution of halogenated alkanes by alkali metal cyanides for the elongation of the molecular chain by one carbon atom:

$$RBr + NaCN \rightarrow RCN + NaBr$$

Another basic reaction is the formation of cyanogen chloride from sodium cyanide and chlorine:

$$NaCN + Cl_2 \rightarrow ClCN + NaCl$$

Trimerization of cyanogen chloride results in the formation of cyanuric chloride (→ Cyanuric Acid and Cyanuric Chloride, Chap. 3), an important raw material for the production of herbicides, pesticides, fungicides, and insecticides. Cyanides are therefore important raw materials for crop-protection agents in the worldwide agricultural market. Many other organic synthetic procedures start with cyanogen chloride as raw material (→ Cyano Compounds, Inorganic, Chap. 4.4).

For a number of fertilizers and other important organic compounds production starts with cyanogen (→ Cyano Compounds, Inorganic, Chap. 5), the dinitrile of oxalic acid, which is made from alkali metal cyanide and copper sulfate, for example:

$$4\,KCN + 2\,CuSO_4 \rightarrow (CN)_2 + 2\,CuCN + K_2SO_4$$

In organic chemistry the cyano group basically acts as a building block which can easily be transformed into a variety of other chemical functional groups, such as carboxylic acids, esters, hydroxylamines, cyanohydrins, and many more. The standard application is to add cyanide to a molecule to modify its structure and functionality. The high-value end products are free of cyanide. The basic equations for the numerous reactions can be described as follows (X = halogen, R = organic group):

$$RX + CN^- \rightarrow RCN + X^-$$

$$RCN \rightarrow RCOOH \rightarrow RCOOR$$

Various inorganic synthetic products are made which still contain cyanide in an unmodified form. However these chemicals have specific characteristics such as colors (e.g., ferrous cyanide products) and do not exhibit the toxicity characteristics of free cyanides.

5.3. Electroplating of Metals

(→ Electrochemical and Chemical Deposition)

The electroplating industry uses silver and gold cyanides for electroplating processes:

$$KCN + AgNO_3 \rightarrow AgCN + KNO_3$$

$$KCN + AuCN \rightarrow K\left[Ag(CN)_2\right]$$

Beside the similar gold cyanide and potassium dicyanoaurate(I) the trivalent gold cyanide compound $K[Au(CN)_4]$ has the advantage of working in lower pH ranges and is able to deposit gold directly onto stainless steel base materials.

Electroplating of platinum metals is performed in cyanide baths and, for special applications, in cyanide melts. The high-temperature electroplating (HTE process) runs in the temperature range of 500 – 600 °C in an eutectic sodium – potassium cyanide mixture under argon gas.

The yellow and red cyanide complexes of bivalent and trivalent iron $K_4[Fe(CN)_6]$ and $K_3[Fe(CN)_6]$ are used to precipitate traces of base metals and to form blue pigments.

In the electroplating of metal surfaces complex metal cyanides are formed in solution or added to a process solution, and the metal from the cyanide complex is precipitated on the metal surface in an electric field. This technology is used to improve the surface characteristics of base metals and inexpensive metals (usually in industrial application).

5.4. Hardening of Metals

Strongly treated steel, such as that camshafts for motors, must be hardened by boron, nitrogen, or carbon. One of the most favorably applied methods is the carbonization of the metals in melts with cyanide. A superficial layer of iron carbide, Fe_3C (martensite) with a depth of several micrometers is formed at a temperature of about 900 °C. By the addition of barium chloride as activator the amount of cyanide could be minimized to some extent. The main chemical reactions of the hardening process are:

$$2\,NaCN + 2\,O_2 \rightarrow Na_2CO_3 + N_2 + CO$$

and

$$3\,Fe + 2CO \rightarrow Fe_3C + CO_2$$

and hence the overall reaction:

$$4\,NaCN + 4\,O_2 + 3\,Fe \rightarrow Fe_3C + 2\,Na_2CO_3 + 2\,N_2 + CO_2$$

The regeneration of such melts is possible with nonhazardous polymeric cyanic acid, azulminic acid $[CNH]_x$, cyanamide NH_2CN, dicyanamide, or melamine under nitrogen atmosphere.

6. Economic Aspects

The most important alkali metal cyanides in terms of production volume are sodium cyanide and potassium cyanide. Potassium cyanide production worldwide amounts to less than 10 % of the sodium cyanide production. The same production facilities can be used for the manufacture of NaCN and KCN.

In Europe, NaCN and KCN are produced at less than ten sites for various purposes. A significant amount is produced for captive use, but the majority is produced for applications within Europe and for export outside Europe.

Cyanide production efficiency is mainly driven by cost-effective production conditions. The production costs are mainly influenced by the costs for the raw materials HCN and NaOH/KOH, which can differ significantly.

In the 1990s the cyanide producer market in Europe consolidated to a significant extent, and a number of production sites have been closed. Existing production sites in Europe as of 2005 follow (asterisk denotes captive use):

Wesseling, Germany	NaCN solution, NaCN solid, KCN solid
Geleen, the Netherlands	NaCN solution
Billingham, United Kingdom	NaCN solution
Ludwigshafen, Germany	NaCN solution
Antwerp, Belgium	NaCN solution
Kolin, Czech Republic	NaCN solid
Pitesti, Rumania	NaCN solution
Seal Sands, United Kingdom*	NaCN solution
Saint-Avold, France*	NaCN solution
Roussillon, France*	NaCN solution

The production capacity of cyanides in Europe is in the range of 90 000 t/a (based on 100 % solid material). Most of this is solid sodium cyanide; a smaller part is solid potassium cyanide. Worldwide sodium cyanide production is estimated at approx. 500 000 t/a.

About 70 % of world cyanide production is used in the gold mining industry. The second biggest application is in industrial chemical synthesis, and third is electroplating together with metal hardening.

In Europe the majority of cyanide production is used in chemical synthesis. The second largest application is electroplating together with metal hardening, and the third is the mining industry.

The differences in prices between NaCN and KCN are mainly reflected in the price differences of the raw materials NaOH and KOH. As KOH is significantly higher in price, KCN is also more expensive than NaCN. Selling prices in Europe for NaCN/KCN are also subject to fluctuation on the world market. Prices were mainly less than 1650 \$/t for NaCN (100 %) and less than 3000 \$/t for KCN (100 %).

7. Best Available Techniques (BAT)

7.1. Processes

All above-mentioned techniques and procedures to produce cyanides (Chap. 2) in solution and in solid form only create a very small absolute contribution to emissions of hazardous chemicals to the environment. In addition, where properly designed wet scrubber systems are utilized to contain the noncondensed gases, there is no contribution to CO_2 emissions. Where incineration or combustion is used, there is an emission of CO_2. In production processes where wet solids are dried prior to compaction, the drying energy is typically provided by gas-fired heaters. The combustion gases from the heater are emitted to the atmosphere according to industry standards for fuel combustion devices. In Germany a typically permitted emission value for NO_x is approx. 1.8 kg/h for such heaters.

All of the above mentioned techniques can basically be considered to meet BAT requirements.

All melt processes must be considered to be very high in energy consumption and also indirectly contribute to CO_2 emissions due to the burning of fossil fuels. However, processes for HCN production, such as the BMA process, have high energy consumption for the formation of HCN, because the reaction of CH_4 and NH_3 (without oxygen) is endothermic and requires heating of the reaction gases to 1200 °C. The energy input necessary is 252 kJ/mol. In contrast the Andrussow process (using oxygen from air) is exothermic and creates energy in the range of 474 kJ/mol. However in the BMA process hydrogen (H_2) is formed, which can be used for the production of a number of downstream products such as H_2O_2, CH_3SH, and others. Also the energy content of H_2 must be taken into consideration positively if it is used to create energy for other processes. By doing this the energy balance of the Andrussow and the BMA process are very similar. Therefore, using HCN from the Andrussow or from the BMA process can be seen as equal regarding the overall energy balance.

Based on these considerations melt processes for the production of cyanides and the production of cyanides based on HCN derived from the BMA process can be judged to be similar with respect to energy consumption and the respective CO_2 release in case organic fuels are burned.

Finally, when cyanides are detoxified by an oxidation process cyanate (OCN^-) is formed and this can be broken down in aqueous solution to ammonium carbonate $(NH_4)_2CO_3$ (depending on the pH of the solution). From this solution ammonia can be released already at slightly alkaline pH (pH equilibrium curve for the system NH_3/NH_4^+ is relevant here). In the end this means that the NH_3 used for the synthesis of HCN is again released as NH_3. The carbon from the hydrocarbons (CH_4) is transferred into carbonates.

Any process leading directly to a shippable solid material which meets the quality and safety standards of the customer industry would be ideal to be considered as BAT. This is the case for the patented process to form fluidized-bed granulates, but this process is not in large-scale operation yet.

As a final conclusion all existing processes for cyanide production can be considered as BAT at present (2005).

7.2. Procedures

Destruction of Cyanides in Waste Gases and Wastewaters (Fig. 6)**.** Due to their toxicity, cyanides are removed from an air stream (3400 m^3/h, 50 mg/m^3 HCN) by using a scrubber with NaOH solution. The solution is circulated between a buffer vessel and the washer. The solution is sampled regularly and exchanged if the content of free OH^- is too low for the absorption of HCN from the air stream. The cyanide solution is then reconditioned with other CN^--rich wastewater streams and used to substitute raw materials (1 m^3/h, 5 % CN^-). A

low-CN^- wastewater stream (15000 m^3/h, 700 mg/m^3 HCN) leaves the reconditioning process. The remaining cyanide is destroyed together with low-CN^- wastewater streams by pH adjustment and oxidative destruction with H_2O_2. The overall efficency is 99.9 %. Detoxification of cyanide at the plant with hydrogen peroxide based technology should be considered as BAT as no salts are produced and the only byproduct is water.

Figure 6. Flow chart of the cyanide destruction in waste gases and wastewaters

Environmental Benefits.
- Removal of HCN/CN^- from waste gases and wastewaters
- Achieved emission values for waste gas (concentration 1 mg/m^3, mass flow 3 g/h) and wastewater (concentration 1.1 mg/m^3, mass flow 2.3 g/h)

Cross-Media Effects.
- Reuse of waste streams as raw materials
- No AOX in wastewater
- No contaminated waste
- Lower energy consumption

Applicability.
- Generally applicable

Economics.
- Cost reduction for wastewater treatment

Driving Force for Implementation.
- Removal of toxic compounds from waste gases and wastewaters

Incineration of Process Air Containing Volatile Organics. A raw material for the process can contain small amounts of volatile organics. In the process, benzene was found in several air streams (2500 m^3/h, variable benzene concentration), which are sent to an air cleaning system. The air streams which contain benzene are identified and separated from the others. The benzene containing air streams are burned in a air heater which is run by natural gas (Fig. 7). The energy from the incineration is recovered. The circulation drying air is heated with this energy. The overall efficiency is 99.9 %.

Figure 7. Incineration of process air containing volatile organics

Environmental Benefits.
- Removal of benzene from waste gases
- Achieved emission values for waste gas (concentration <1 mg/m^3, mass flow 0.4 g/h)

Cross-Media Effects.
- Reduced consumption of natural gas by using benzene-containing air
- Heat from incineration is recovered in the process

Applicability.
- Generally applicable

Economics.
- Reduction of energy costs
- Comparatively low investment costs

Driving Force for Implementation.
- Removal of toxic compounds from waste gases

Cleaning of Equipment Contaminated with Cyanides in Totally Enclosed Systems. During production, solid cyanide builds up in pipelines, machines, and vessels and can thus cause a blockage. In all equipment, a cleaning-in-place (CIP) system was installed (Fig. 8). In case of a blockage, the equipment can be easily rinsed and cleaned in a totally closed system. No contaminated emissions to the environment or exposure of workers occurs. The rinsing water containing cyanide (15 m^3/h, variable cyanide concentration) is collected in a closed piping system and stored in vessels. The rinsing water is then recycled into the process to reduce the use of raw material. In addition, solid waste containing solid cyanide salts (i.e., off-spec product, waste) can be dissolved in the collecting vessels and recycled in the process. Thus the amount of hazardous wastes is reduced. The overall efficiency is 99 %.

Figure 8. Cleaning of equipment contaminated with cyanides in totally enclosed systems

Environmental Benefits.
- No solid waste containing cyanides
- Recycling of solid waste within the process
- No emissions during cleaning

Cross-Media Effects.
- Reduced amount of rinsing water through CIP system
- Lower energy consumption

Applicability.
- Generally applicable

Economics.
- Cost reduction for wastewater treatment
- Cost reduction for raw materials

Driving Force for Implementation.
- Reduction of emissions to environment and workplace

Removal of HCN and NH_3 from Waste Gases. Due to their toxicity, HCN and ammonia are removed from gas streams (3400 m^3/h, 50 mg/m^3 HCN, 250 mg/m^3 NH_3) using an alkaline scrubber with NaOH solution and an acidic scrubber with sulfuric acid. For each scrubber the solution is circulated between a buffer vessel and the washer. The solution of each washer is sampled regularly and exchanged if the content of free OH^- is too low for the absorption of HCN from the air stream or if the free H_2SO_4 concentration is too low for the absorption of ammonia. The cyanide solution of the alkaline washer is recycled to the process to substitute raw materials. The ammonium sulfate solution of the acidic washer is recycled in a nearby plant to produce fertilizer. The secondary containment of the acidic washer is strictly separated from the secondary containment of the alkaline washer and the rest of the production building (Fig. 9). If acids came into contact with solutions containing cyanide, HCN would be emitted to the environment and workplace. The overall efficiency is 99.9 %.

Figure 9. Removal of HCN and NH_3 from waste gases

Environmental Benefits.
- Removal of HCN/NH_3 from waste gases
- Strict separation of acidic and alkaline containment reduces emissions in case of an emergency
- Achieved emission values for HCN (concentration 1 mg/m^3, mass flow 3 g/h) and NH_3 (concentration 1.2 mg/m^3, mass flow 3 g/h)

Cross-Media Effects.
- Reuse of washer solutions as raw materials
- No wastewater from scrubbers
- Lower energy consumption
- Simple and reliable control of efficiency by regular analysis of the solution

Applicability.
- Generally applicable

Economics.
- Low operating costs

Driving Force for Implementation.
- Removal of toxic compounds form waste gases

Returnable Packages for Solid Cyanides. Besides one-way packages (i.e., steel drums, bulk bags) returnable packages are used for the transport of cyanides. In a filling line, the packages are filled with cyanides. After the customer has emptied the packages, the sealed contaminated packages are returned. A second option is that the part of the package that did not come into contact with cyanide is disassembled and returned to the filling line. Here it is checked and assembled again. Cyanide customers can be equipped with unloading devices to unload the packages in a closed system.

Environmental Benefits.
- Reduction of cyanide dust emissions during unloading
- Reduction of the amount of contaminated packages and waste

Cross-Media Effects.
- Higher safety standards in workplace during unloading
- Return transport of packaging to the filling station leads to additional fuel consumption

Applicability.
- Generally applicable

Economics.
- Reduction of packaging costs

Driving Force for Implementation.
- Reduction of contaminated waste

Transport of Solid Cyanide. Besides one-way packages (i.e., steel drums, bulk bags) returnable packages are used for the transport of cyanides. In a filling line, the vessels that are normally used for a liquid transport are filled with solid cyanides. For the unloading the cyanide customer connects two hoses to the vessel. The solid cyanide is dissolved by circulating water through the vessel, which has built-in nozzles. The cyanide is unloaded in a closed system.

Environmental Benefits.
- Reduction of cyanide dust emissions during unloading
- Reduction of the amount of contaminated packages and waste

Cross-Media Effects.
- Higher safety standards in the workplace
- Greater safety through the transport of solid material instead of liquid solution
- Return transport to the filling station leads to additional fuel consumption

Applicability.
- Generally applicable when cyanide is dissolved in water

Economics.
- Reduction of packaging costs

Driving Force for Implementation.
- Reduction of contaminated waste

Operation of Sodium Cyanide Plant. The operation of a sodium cyanide plant requires numerous and frequent observations of operating parameters, and adjustment of the process controls to ensure safety and environmental control. A computer process control system can monitor hundreds of process parameters many times per minute, and automatically adjust parmameters to ensure a safe and environmentally sound operation. Using computerized process control, automatic interlocks can be implemented to prevent

overfilling tanks, emitting excess contaminants to the atmosphere, and minimize the generation of wastewater.

Environmental Benefits.
- Reduction of cyanide emission
- Reduction of contaminated wastewater

Cross-Media Effects.
- Higher safety standards in workplace
- Lower emissions in air and water streams
- Reduced need to "open" the process for cleaning

Applicability.
- Generally applicable for solid sodium cyanide production facility

Economics.
- Reduction of waste treatment

Driving Force for Implementation.
- Reduction of emissions

Double Containment of Solid Sodium Cyanide Plant. In a solid sodium cyanide production facility, sometimes there are leaks, dust, equipment wash water, etc. which can result in sodium cyanide solution being present on the floor of the production plant. Plants constructed of concrete or other traditional civil construction materials are subject to potential cracking. Through these cracks, the cyanide-contaminated water can leach into the ground and possibly groundwater. Providing double containment for the ground floor and sumps reduces the potential for cyanide to be released to the soil or groundwater.

Environmental Benefits.
- Reduction of soil contamination
- Reduction of contaminated civil construction materials

Cross-Media Effects.
- Higher safety standards in workplace
- Greater safety of soil and groundwater

Applicability.
- Generally applicable when cyanide solutions are present on the ground floor

Economics.
- Reduction of material losses

Driving Force for Implementation.
- Improved assurance of no leakage of cyanide solution to the soil

Storage of Solid Alkali Metal Cyanide. Sodium cyanide is stored in UN-certified packages for the transport of dangerous goods in specially designed storage buildings. The building is fenced and locked to prohibit the access of unauthorized persons. Alkali metal cyanide easily dissolves in water. Therefore the building is constructed such that no rainfall or surface water can enter the building. Additionally, the use of water is prohibited for fire fighting. Alkaline foam is used instead. The use of acidic foams is also prohibited since HCN can be liberated by this kind of foam.

Environmental Benefits.
- Reduction of soil and water contamination
- Reduction of contaminated civil construction material

Cross-Media Effects.
- Higher safety standards in workplace
- Higher security standards to limit access to the cyanides

Applicability.
- Generally applicable where cyanide salts are stored in packages

Economics.
- Comparatively low construction costs

Driving Force for Implementation.
- Enhancing safety and security standards

Training of Personnel in a Cyanide Plant. To operate a cyanide plant a high level of knowledge and training is necessary. A complex process, modern technologies, highly toxic substances, and emergency situations place a lot of stress on the operators. To ensure that incidents and accidents are kept to a minimum and to reduce mistakes in emergency situations to a minimum special education and training programs are necessary. Besides a sound basic education in chemical operations, personnel are trained in different level of jobs over the years. The skills are tested in written or practical exams. Additionally, all operators are trained regularly in emergency response, occupational, product, and transportation safety regulations.

Environmental Benefits.
- Reduced risk of emission to air, water, and soil in case of emergencies

Cross-Media Effects.
- Higher education level of personnel

Applicability.
- Generally applicable

Economics.
- Better education leads also to a reduction in production costs

Driving Force for Implementation.
- Enhancing safety standards

Computational Fluid Dynamics (CFD) is a numerically based tool for the prediction of flow field, concentration and temperature distribution. Its main parts are mathematical modeling, discretization, numerical solution of the discretized equations and the interpretation of numerical results.Basic equations in all mathematical models for CFD are balances for momentum and total mass determining velocity, pressure and density field. Depending on the case considered they are supplemented by mass balances for single species and a heat balance. Additional models are required to describe, e.g. turbulence, multiphase flows, chemically reactive systems and other special cases.Basis for the discretization of the balance equation is the discretization of a space — the grid generation. Most codes can handle unstructured grids. Nevertheless, certain requirements concerning grid structure have to be fulfilled to get stable convergence and an accurate solution. Traditionally, most CFD codes use finite volume discretization for the balance equations, even if finite element algorithms are of increasing relevance for simulations with adaptively moving grids and for coupling CFD with structural dynamics simulations. A new approach for simulations with high resolution in space and time is the lattice Boltzmann method.

Finally, the numerical results have to be graphically presented and interpreted. Because of the huge amount of numerical data provided by each simulation this cannot be done with a general method. It must always be analysed in reference to a certain research question. Errors caused by the model formulation and by the numerical scheme have to be analyzed in order to judge the accuracy of a simulation. Quantitative estimates are required for an adequate interpretation of the results.

1. Introduction

The increasing pressure on development time and product quality in industrial process development stimulates the application of numerical methods in addition to traditional experimental ones. In many cases the numerical tools can save time and costs if they are used complementary to experimental methods. The simulation tool for modeling fluid dynamic processes is called computational fluid dynamics (CFD). Highly complex mathematical models are needed for a sufficient description of the relevant interactions in reactive flows occurring on different timescales. Even if not all aspects can be considered in detail to keep the equation system in a manageable frame, the complex mathematical models are far from being solvable analytically. Therefore, numerical methods play an important role in CFD, and many users associate CFD mainly with its numerical aspects. But the subject is defined much more widely: formulation of the mathematical model, visualization, and interpretation are all essential parts of the tool.

2. Procedure

This chapter sketches the general steps of a CFD simulation. It gives an overview of the procedure and the relation of the individual parts. The points mentioned here are described in more detail in the following chapters.

As with all investigation methods, the formulation of the exact question is a crucial point for the entire CFD procedure. The question includes the target value and its accuracy, the dependencies of importance and possible approximations and assumptions which can be made. Also the range in space and time to be considered is a part of it. All significant physical parameters or the range of their variation must be specified together with the physical state at the boundaries and at the initial time. The formulation of the question determines the effort and the time required to solve the problem and should be therefore as strict as necessary and as weak as possible.

The mathematical model can be formulated on the basis of the question posed. Its central elements are balance equations for mass, momentum and energy. These are supplemented by additional model equations if necessary. All partial differential equations require initial and boundary conditions for their solution. Parameters and constants in the equations have to be specified in a way that the model is mathematically closed. For this purpose, additional laws, like an equation of state or temperature dependencies of physical properties (e.g., density, viscosity) may be required. Not always can the most exact mathematical formulation be solved with reasonable effort. In such cases, additional model assumptions such as averaging procedures, reduction of the number of variables or restriction of the range in space and time considered must be introduced.

The resulting system of differential, integral and algebraic equations is too complex to be solved analytically. Therefore, numerical algorithms are applied to derive a system of linear algebraic equations which provides an approximative solution of the original mathematical model. In most cases this discretization is performed by using the finite volume method or the finite element method. Specialized methods exist for certain applications. A relatively new alternative to classic discretization algorithms are statistical methods like the lattice Boltzmann method.

As a result of the great complexity of the mathematical model, the numerical solution of the governing equations must be postprocessed to extract the information necessary to answer

the original question. Most often this information can best be presented in a graphical plot, but the data to be plotted are usually not the direct solution of the model. Relevant data must be selected, linked, transformed, and in some cases statistically treated and normalized to create a data set which allows the user to answer the question.

Last but not least, the accuracy of the numerical result must be judged, even if the simulation is not erroneous in an obvious sense. Starting from the setup of the mathematical model over all numerical steps, up to postprocessing, inaccuracies are introduced or at least accepted. Only a rough quantitative error estimation can prove whether the solution provided is accurate enough for the question considered.

3. Modeling

The central CFD modeling approach is to balance momentum, mass and heat. This approach is based on the continuity hypothesis which states that all balance quantities and physical parameters change continuously within each phase. Consequently, limiting considerations for infinitesimally small volumes never consider changes at the molecular level. Discontinuous jumps are found only at interfaces. Therefore, in some points, modeling of multiphase systems requires different approaches than modeling of single-phase systems.

For an easier understanding of the following discussion a few terms will be defined:

- Balance quantities: Quantities governed by laws of conservation can be balanced. In general, mass, momentum and energy are such balance quantities. For detailed considerations masses of different chemical species or different kinds of energy can be balanced separately. In such balances source terms for possible conversions appear. Balance quantities are extensive values.
- Transport quantities: While the basic step of balancing is an integral consideration of the balance quantities, differential transport equations can be derived from the original balances. Transport equations describe the distribution and transport of intensive values, either mass-based (mass fraction, specific energy) or volume-based (density, concentration), which are the so-called transport quantities.
- Independent variables: Independent variables in transport equations are normally the three spacial directions and time. In special cases symmetry can be used to reduce the number of spacial directions; in the case of stationary considerations, time is not considered. For certain model approaches additional independent variables must be included. In probability density models, e.g. for micromixing, the species composition is an additional independent variable, in population balances particle properties such as the characteristic diameter take on this functionality.
- Parameters: All known values in the transport equations — besides transport quantities and independent variables — are called parameters. "Known" must be understood in a mathematical sense: the solution of the equations is only possible if values for the parameters are given. In the physical sense the determination of these values might be problematic or only possible with the help of an additional equation.

3.1. Transport Equations

Transport equations are derived on the basis of balances. For the general transport quantity ϕ the transport equation reads:

$$\begin{array}{ccccccc} \dfrac{\partial \phi}{\partial t} & = & -\nabla(\mathbf{v}\phi) & - & \nabla \mathbf{J}_\phi & + & S_\phi \\ (a) & = & (b) & + & (c) & + & (d) \end{array} \tag{1}$$

Term (a), the time derivative, codes transient changes. Term (b) models the convective transport with $\mathbf{v}$ being the convective velocity. Term (c) in this general form is the molecular transport term including the molecular flux vector $\mathbf{J}_\phi$. In certain cases, in particular in turbulence modeling, structurally similar terms can occur which are numerically treated in the same way but have different physical meanings. Finally, term (d) is the source term. The kinds of sources which occur depend strongly on the transport quantity ϕ. In the momentum balance these are forces, in the energy balance these are exchange rates to other types of energy, and in mass balances for single species these are conversion rates due to chemical reactions.

Detailed derivations and discussions of the transport equations can be found in [1] (see also Transport Phenomena). Only a short overview is presented here.

Continuity Equation. A basic physical law is the conservation of mass. From this the continuity equation can be derived:

$$\frac{\partial \rho}{\partial t} = -\nabla\ (\rho \mathbf{v}) \tag{2}$$

As there is no molecular mass transfer relative to the convective velocity (with its mass-based definition) and no source of mass in a nonrelativistic system, this equation contains only terms (a) and (b) of Equation 1 with density ρ being the transport value.

Equation of Motion. CFD considers transport phenomena in fluids, so the convective velocity is a central quantity. This becomes obvious also from Equation 1, where velocity is the only general, ϕ-independent value. The velocity is determined by the equation of motion:

$$\frac{\partial \rho \mathbf{v}}{\partial t} = -\nabla\ (\rho \mathbf{v}\mathbf{v}) - \nabla\, \boldsymbol{\tau} - \nabla p + \rho \mathbf{g} \tag{3}$$

The velocity itself is not the transport quantity here but rather the volume-based momentum $\rho \boldsymbol{v}$. The stress tensor $\boldsymbol{\tau}$ plays the part of the molecular flux. It is a function of the velocity gradient, but this functionality can not be expressed in a general form because it depends on the rheologic properties of the fluid. In many applications a Newtonian fluid can be assumed, and τ can be expressed in the following way:

$$\boldsymbol{\tau} = \mu[\nabla \mathbf{v} + (\nabla \mathbf{v})^{\mathbf{T}}] + \left(\kappa - \frac{2}{3}\mu\right)(\nabla \cdot \mathbf{v})\delta \tag{4}$$

where μ is the viscosity, which is independent of shear stress and time in Newtonian fluids, and κ is the dilatational viscosity, which in most real cases has no influence on the flow.

The last two terms of Equation 3 are the source terms to be considered in most cases. The pressure term is of greatest importance. It has a dual role in the structure of the equation. As mentioned, it can be seen as a source term, but it also could be counted as a special type of stress and included together with τ in a general stress term. The first concept is applied here because it provides a more suitable structure for the discussion of numerical methods.

Gravity acts in all systems and is therefore also written here. In special cases other forces acting on a fluid like electromagnetic forces or centrifugal forces also must be considered.

Two things complicate the numerical handling of the equation of motion. The first is the nonlinear structure of the convective terms. While in other transport equations the velocity can be handled like a parameter, in the equation of motion it is the unknown. The second problem results from the pressure term. There is no transport equation available for pressure. In compressible fluids an equation of state is used additionally which allows one to calculate the pressure if the density field is known from the equation of continuity. The solution of these three coupled equations (one of which has three components) is numerically not handsome, but possible without significant problems. In incompressible systems the density is constant and an equation of state cannot be used to determine the pressure. The remaining equation for the pressure is the equation of continuity, but it does not contain the pressure. The relation can be described such that only the velocities which satisfy the equation of motion with the right pressure gradient also satisfy the equation of continuity.

Navier–Stokes Equations. A special and commonly used version of the equation of continuity and the equation of motion are obtained for Newtonian fluids with constant density and constant viscosity. The equations simplify to:

Equation of continuity:

$$\nabla \mathbf{v} = 0 \tag{5}$$

Equation of motion:

$$\rho \frac{\partial \mathbf{v}}{\partial t} = -\rho \mathbf{v} \nabla \mathbf{v} + \mu \nabla^2 \mathbf{v} - \nabla p + \rho \mathbf{g} \tag{6}$$

This equations are called Navier–Stokes equations. They are of restricted validity because changes in temperature as well as changes in the chemical composition effect density and velocity. Nevertheless, they are a reasonable approach in many cases.

Concentration Equation. The equation of continuity results from the overall mass balance. If a multicomponent system is considered and

the concentration of the different species is of interest for the simulation, separate transport equations must be solved for them. As the global mass balance is solved in all cases, the number of additional equations needed for a complete description is one less than the total number of species in the system. The transport equation for a concentration c reads:

$$\frac{\partial c}{\partial t} = -\mathbf{v}\nabla c + \nabla(D\nabla \mathrm{c}) + S_{\mathrm{c}} \tag{7}$$

where D is the molecular diffusion coefficient and S_{c} is the source term resulting from a chemical reaction. It is expressed via the chemical reaction kinetics, which in many cases include nonlinear expressions and dependencies between concentrations of different chemical species.

Energy Equation. Formulating energy equations is a large area because there are many different forms of energy which can be converted into each other. For CFD the equation of the internal energy is usually considered to obtain an equation for the temperature profile. For the application of turbulence modeling, a certain part of the kinetic energy is of interest. This second case is discussed in Section 3.3 only the internal energy is considered here. Internal energy covers the kinetic energy of atomic and molecular motion, potential energy of intermolecular interactions, energy of chemical bonds, and nuclear energy. Not all aspects of this energy can be determined absolutely. Therefore, only differences in the internal energy between two states are discussed. Balancing of the internal energy gives:

$$\begin{aligned} \frac{\partial \rho u}{\partial t} &= -\nabla(\rho u \mathbf{v}) - \nabla \dot{\mathbf{q}} - (\boldsymbol{\tau}:\nabla \mathbf{v}) - p(\nabla \cdot \mathbf{v}) + S_{\mathrm{u}} \\ (a) &= (b) \qquad + (c) \quad + (d) \qquad + (e) \qquad + (f) \end{aligned} \tag{8}$$

with

(a) = temporal change
(b) = convective transport
(c) = heat conduction
(d) = increase by viscous dissipation
(e) = increase by compression
(f) = conversion from other types of energy

If an incompressible fluid is considered, in addition viscous dissipation, radiation and other kinds of energy conversion can be neglected, and if the mixing enthalpy is also negligible, the only potential source is the enthalpy of a chemical reaction S_{hr}. Density, thermal conductivity, and heat capacity values are calculated for the mixture in the case of a multicomponent system. With these assumptions the temperature equation can be derived in the form of a commonly used equation:

$$\frac{\partial \rho c_p T}{\partial t} = -\mathbf{v}\nabla(\rho c_p T) - \nabla(\lambda \nabla \rho c_p T) + S_{hr} \tag{9}$$

where c_{p} is the heat capacity and λ the thermal conductivity. If the assumptions do not hold as described above, extended forms of the temperature equations must be derived.

3.2. Initial and Boundary Conditions

Partial differential equations cannot be solved without initial and boundary conditions. In a mathematical sense this can be interpreted such that the solving of a differential equation requires its integration, and to perform this the integration constants must be determined. Consequently, the number of additional conditions needed for each independent variable is equal to the number of derivatives. Therefore, in time only one condition is needed, which in most cases is given at the initial time, while for the space coordinates two conditions are required, which are realized normally by one condition at each boundary point.

For the initial conditions values of the transport quantities ϕ must always be given. These values may vary in space but cannot be a function of ϕ.

Three different types of boundary conditions are possible:

Dirichlet condition	
$\phi\|_{\mathrm{BC}} = C_{\mathrm{BC1}}$	fixed value of ϕ given at the boundary
Neumann condition	
$\frac{\partial \phi}{\partial n}\|_{\mathrm{BC}} = C_{\mathrm{BC2}}$	derivative of ϕ normal to the boundary is given
Cauchy condition	
$\frac{\partial \phi}{\partial n}\|_{\mathrm{BC}} + C_{\mathrm{BC3}}\,\phi\|_{\mathrm{BC}} = C_{\mathrm{BC4}}$	combination of value and derivative of ϕ is given

In a finite region of the boundary a Dirichlet condition is required. The use of these boundary

conditions can be segregated in relation to the physical nature of boundaries. The ones most often used are presented here, but for special flow situations other types can also be defined. It is not always easy to find the expression required, and in some cases a setup is more easily obtained by moving the boundary location than by constructing a complex formulation at the original location. An example is shown in Figure 1.

Figure 1. Location of boundary conditions

- Inlet: It is assumed that the conditions at the inlet are known. Therefore, fixed values are given at the inlet for all transport quantities. These fixed values may vary along the inlet, e.g., a parabolic velocity profile can be given for a laminar flow in a tube.
- Wall: Most model systems are bounded at least partly by solid walls. They can be fixed or moving (e.g., wall and stirrer of a stirred vessel). Walls considered here are impermeable for mass fluxes but may possibly conduct heat. To prevent convective fluxes through the wall the normal velocity component is set to zero or equal to the normal velocity of the moving wall. Assuming no slip conditions, the tangential velocity is equal to the wall velocity, which is zero with fixed walls. If slip is considered, the gradient of the tangential velocity components normal to the wall is zero. To avoid diffusive fluxes through the wall the concentration gradient normal to the wall is set to zero.
  For heat transfer different types of walls must be considered. The definition of temperature boundary conditions at walls is an approximation in most cases, because neither the physical conditions are well known there nor are they easy to control. Adiabatic walls are modeled by using a zero temperature gradient normal to the wall. At walls of fixed temperature this temperature is given as boundary condition. Heat fluxes across a wall can be described by using Neumann or Cauchy conditions.
- Outlet: No assumptions about the quantities of the transport values can be made for outlet conditions. However, it is assumed that the flow is uniform and no further sources occur. In that case velocities tangential to the outlet are zero. For all other unknowns (normal velocity, concentrations, temperature) zero gradients normal to the outlet are used. Furthermore, for incompressible flows the mass flow at each outlet must be specified to preserve the total mass.
  It is not always easy to find a location at which outlet boundary conditions can be specified with sufficient accuracy. Special problems occur in turbulent flows if vertex structures are not averaged but resolved and the assumptions for the velocity field do not hold. In such a case, boundary conditions for the pressure are stated instead of velocity conditions. The strong coupling between pressure and velocity described in context of the equation of motion allows one to solve these equations with this type of boundary conditions.
- Symmetry: Some systems show symmetries which allow one to reduce the model space and consequently the numerical effort. Symmetry can be utilized if it holds not only for the geometry, but also for the flow and for all transport variables.
  Symmetry is given when all gradients normal to the symmetry plane are zero and the velocity component normal to the symmetry plane is zero, too.

3.3. Turbulent Flow

While laminar flow is characterized by parallel stream lines, in a turbulent flow vortex structures of a large size range cause highly frequent fluctuations in all transport variables. All the equations introduced up to now are valid in laminar as well as in turbulent flows, as long as the conditions mentioned hold. The greatest problem in sim-

ulations of turbulent flows is that the resolution of the high-frequency fluctuations requires a fine numerical grid and small time steps. The number of grid cells N needed for a three-dimensional simulation can be estimated by

$$N=5^3 Re^{9/4} \tag{10}$$

where Re is the Reynolds number of the flow. Such simulations of turbulent flows, called *direct numerical simulations* (DNS) are possible only for small academic cases and relatively low Reynolds numbers with current (2004) computing power.

In most cases the exact structure of the turbulent flow is of minor interest and information on local averaged values is sufficient. Unfortunately, such an averaging can not be done in a simple way because the course-scale structure of the flow interacts strongly with the small-scale structure. Special attention must be given to chemically reactive flows. Chemical reactions can take place only if the species are mixed on the molecular scale. A model averaging this scale may overestimate the rate of fast chemical reactions.

Two general modeling approaches for turbulent flows are used nowadays: *Reynolds averaging* (Reynolds-averaged Navier–Stokes RANS) and *large-eddy simulations* (LES). RANS modeling is based on averaging all transport quantities over all scales of turbulent fluctuations. This allows one to use relatively coarse grids and can be applied to geometrically large systems with reasonable effort. The influence of turbulent structures is included in additional models. Large-eddy simulations work with a grid size which allows direct resolution of the large-scale part of the turbulence structures. Since the large eddies contain the majority of the turbulent energy, the return in accuracy is superproportional to the increase in effort with this approach. The filter width is a function of the grid spacing and can therefore be influenced by the user. Nevertheless, subgrid-scale models (SGS models) are required also for LES. The numerical effort for LES is significantly larger than for RANS simulations and can be handled at the moment only on high-performance parallel computers. Figure 2 gives an impression of the resolution of turbulent eddy structures by the different methods.

LES and RANS are illustrated in more detail for the equation of motion. Concentration and energy equations can be handled in a similar way, but all turbulence models are developed in the first step for momentum transport. Thus the mass and energy transport models use proportionality approaches, in most cases based on the parameters computed for momentum transport.

Reynolds Averaging. Reynolds averaging is based on the assumption that scales of the main flow and of turbulent fluctuations differ significantly. Therefore, each transport quantity can be split up into a time-averaged value $\overline{\phi}$ and a fluctuating value $\phi\prime$ in such a way that possible macroscale fluctuations of $\phi\prime$ are included in $\overline{\phi}$ while turbulent fluctuations are covered by $\phi\prime$:

$$\phi=\overline{\phi}+\phi' \tag{11}$$

In accordance with the goal of RANS to obtain averaged values, the transport equations are averaged. This yields for the Navier–Stokes equations:

$$\begin{aligned} \nabla\,\overline{\mathbf{v}} &= 0 \\ \rho\frac{\partial\overline{\mathbf{v}}}{\partial t} &= -\rho\overline{\mathbf{v}}\nabla\overline{\mathbf{v}}-\nabla\boldsymbol{\tau}_t+\mu\nabla^2\overline{\mathbf{v}}-\nabla\overline{p}+\rho\mathbf{g} \end{aligned} \tag{12}$$

where an additional term including the *Reynolds stress tensor* $\boldsymbol{\tau}_{\mathrm{t}}$ occurs.

$$\boldsymbol{\tau}_t=\rho\mathbf{v}'\times\mathbf{v}'=\begin{pmatrix} \rho\overline{v'_x v'_x} & \rho\overline{v'_x v'_y} & \rho\overline{v'_x v'_z} \\ \rho\overline{v'_y v'_x} & \rho\overline{v'_y v'_y} & \rho\overline{v'_y v'_z} \\ \rho\overline{v'_z v'_x} & \rho\overline{v'_z v'_y} & \rho\overline{v'_z v_z} \end{pmatrix} \tag{13}$$

With this term the averaged equation of motion is not closed because the velocity fluctuations are unknowns.

There are a large number of approaches to model the Reynolds stress tensor. To explain all of them is beyond the scope of this article. A detailed presentation is given in [2]. Therefore, only the most commonly used concept of the eddy viscosity approach together with the k—ε model will be sketched. The effect of the Reynolds stress tensor can be interpreted in analogy to the Newton stress tensor [3]. Therefore, it can be expressed proportionally to the gradient of the averaged velocity with a proportionality factor μ_{t} called *eddy viscosity*:

$$\boldsymbol{\tau}_t=\mu_t[\nabla\overline{\mathbf{v}}+(\nabla\overline{\mathbf{v}})^{\mathbf{T}}]-\frac{2}{3}\rho k\delta \tag{14}$$

a) Direct numerical simulation b) Large eddy simulation c) Reynolds averaged simulation

Figure 2. Resolution of turbulent eddy structures by different modeling approaches
a) Direct numerical simulation; b) Large-eddy simulation; c) Reynolds-averaged simulation

where δ is the unit tensor and k is the turbulent kinetic energy defined by

$$k=\frac{1}{2}\overline{\mathbf{v}'\cdot\mathbf{v}'} \tag{15}$$

In contrast to the molecular viscosity, μ_t is the *eddy viscosity*, which is not a material constant but depends on the flow structure. The k—ε model expresses this dependence as a function of the turbulent kinetic energy k and its dissipation rate ε:

$$\mu_t=C_\mu\rho\frac{k^2}{\varepsilon} \tag{16}$$

with

$$\varepsilon=\frac{\mu}{2\rho}\overline{|\nabla\mathbf{v}'+\nabla\mathbf{v}'^{\mathbf{T}}|^2} \tag{17}$$

and k and ε computed by their own transport equations. The original model [4] uses the following form:

$$\begin{aligned}\frac{\partial\rho k}{\partial t} &= -\nabla(\overline{v}\rho k) + \nabla(\tfrac{\mu_t}{\sigma_k}\nabla k) + \hat{P} - \rho\varepsilon\\ \frac{\partial\rho\varepsilon}{\partial t} &= -\nabla(\overline{v}\rho\varepsilon) + \nabla(\tfrac{\mu_t}{\sigma_\varepsilon}\nabla\varepsilon) + C_{\varepsilon1}\tfrac{\varepsilon}{k}\hat{P} - C_{\varepsilon2}\rho\tfrac{\varepsilon^2}{k}\end{aligned} \tag{18}$$

with the production term $\hat{P}$ defined as

$$\hat{P}=-\frac{\mu_t}{2}|\nabla\overline{\mathbf{v}}+\nabla\overline{\mathbf{v}^{\mathbf{T}}}|^2 \tag{19}$$

The constants of the model are $C_\mu = 0.09$, $C_{\varepsilon1} = 1.44$, $C_{\varepsilon2} = 4.92$, $\sigma_k = 4.0$, $\sigma_\varepsilon = 1.3$.

The k—ε model is valid for fully developed isotropic turbulence. If this condition is not given, either extended RANS models or LES are required for an acceptable flow prediction.

Large-Eddy Simulations. A high-accuracy alternative to Reynolds averaging is given by large-eddy simulations. In this approach the transport values are filtered with a filter function $G(\mathbf{x},\mathbf{x}')$:

$$\hat{\phi}(\mathbf{x})=\int G(\mathbf{x},\mathbf{x}')\phi(\mathbf{x}')\,\mathrm{d}\mathbf{x}' \tag{20}$$

where G describes the influence of the value of ϕ in position $\mathbf{x}'$ on the filtered value $\hat{\phi}$ at position $\mathbf{x}$. Several forms of G are possible, but it is always a function of the grid size.

Filtering the equation of motion gives:

$$\rho\frac{\partial\hat{\mathbf{v}}}{\partial t}=-\rho\hat{\mathbf{v}}\nabla\hat{\mathbf{v}}-\nabla\boldsymbol{\tau}^s+\mu\nabla^2\hat{\mathbf{v}}-\nabla\hat{p}+\rho\mathbf{g} \tag{21}$$

In this equation the subgrid-scale Reynolds stress tensor $\boldsymbol{\tau}^s$ occurs. Its meaning is analogous to the Reynolds stress tensor in RANS but it considers only the effect of unresolved subgrid-scale structures.

Equation 21 can be solved only if $\boldsymbol{\tau}^s$ is expressed as a function of filtered values. For this purpose so-called subgrid-scale models (SGS models) are used.

SGS models of the Smagorinsky type are widespread [5]. They are similar to the eddy viscosity models in RANS, apart from the fact that they consider only sub-grid scale effects. In their structure they do not use information about the eddy structure of the resolved scales. Similarity models like that in [6] are based on the assumption that there is a similarity in the eddy structures of different scales. Therefore, the analysis of the resolved structure can be used to model the subgrid-scale. These models fail to describe dissipation at the smallest eddy scales, because this effect is not found at larger scales. So they have to be combined with other models to cover this aspect. Dynamic models, e.g., [7, 8] are based on this idea and extend upon it. For this approach two simulations on different grids are carried out. The SGS model is adapted to the differences in the predictions of both models. In this way parameters of the SGS scale model can be varied in time and space and dissipation effects are described. Such models are interesting

Figure 3. Modeling micromixing in a computational cell with probability density function approach
a) Distribution of species A (black) and B (white) in a turbulent flow with incomplete micromixing; b) Probability density function of mixing between A and B

for cases in which constant parameters are only a rough approximation. The major drawback of this method is its numerical effort, which is significantly higher than for the other methods.

Micromixing Models. If systems with fast chemical reactions are to be simulated, a description of the mixing state on the microscopic level is required. Neither Reynolds averaging nor large-eddy simulation provides such an description because they average or filter small-scale fluctuations. A remedy is the use of micromixing models which provide information about the micromixing quality as a function of turbulence quantities, like eddy viscosity or turbulent kinetic energy dissipation.

A widespread micromixing model is the probability density function approach (PDF) [9, 10]. It considers the possible mixing states of a fluid of certain composition and gives for each computational cell a probability density function for each state in such a away that the integral composition in this cell is satisfied. For a mixture of only two species A and B this is shown in Figure 3. The local probability density functions are computed from transport equations for the PDF.

Each mixing state is related to a certain chemical reaction rate. The integral of the reaction rates over the whole composition space gives the total reaction rate in the appropriate numerical cell.

Alternative micromixing models are

- Eddy break up model [11]: This is a simple empirical model which assumes binary chemical reaction with only one product. It is mainly applied for the modeling of combustion.
- Flamelet model [12, 13]: This model assumes chemical reaction in a two-dimensional laminar layer. It was developed for premixed and nonpremixed flames with a different definition of the reaction layer for the two cases.
- Engulfment model [14]: This model assumes that a fluid is mixed into another of different composition by formation of a rotational cylinder. Within the cylinder diffusion is the dominant mixing process and the composition changes proportionally to the change in cylinder size.

3.4. Multiphase Approaches

Multiphase systems are characterized by interfaces at which the fluid properties change discontinuously. This requires extensions of the model approaches introduced up to now for their application to multiphase systems. At the beginning of this chapter multiphase systems will be classified to describe the appropriate model for each type.

One type of classification refers to the geometric structure of the system (see Figure 4). If one phase consists of solid or fluid particles with a small size compared to the total system the system is called a *disperse system*. The particles form the disperse phase while the other phase is called the continuous one. For modeling disperse systems, an extended form of the continuum hypothesis is applied. Properties of both phases are considered to be continuously

Figure 4. Geometric structure of multiphase systems

distributed over the whole system; specific properties of single particles are not relevant. The central property in that case is the volume fraction α which for phase *i* is defined as the ratio of the volume V_i of this phase and the total volume V:

$$\alpha_i = \frac{V_i}{V} \tag{22}$$

The sum of all volume fractions must be unity:

$$\sum_i \alpha_i = 1 \tag{23}$$

The assumption that the continuum hypotheses holds for disperse systems implies that changes of properties in a particle are not resolved. This means, e.g., in a temperature distribution that each particle is characterized by a mean temperature, but the different mean temperatures of all particles determine a particle temperature field of the system. If this approach is insufficient for the description of a system, e.g., because the temperature gradient at the interface is needed to determine the heat transfer between the phases exactly, it cannot be modeled with the approach for disperse systems.

An important property of disperse systems is the size distribution. Many phase interactions like buoyancy force or heat transfer rate depend on particle size, and therefore the particle size distribution is needed to determine these interactions exactly. The easiest case from the point of modeling are monodisperse systems; which all particles have the same size. For some applications the differences in the interactions do not need to be resolved, and this approach can be used. If the size distribution has to be considered the particle size becomes an additional independent variable in the system, which increases the complexity of the mathematical treatment significantly. Size distributions are relevant for all cases where the size range of the particles is very wide or the size distribution changes in the course of the process, e.g., by nucleation, evaporation, agglomeration, or similar processes. The computation of particle size distributions is based on the solution of population balances. This model approach is not discussed here further, but details can be found, e.g., in [15 – 17].

Another characteristic of a disperse system is the relative velocity between the phases. If the differences in gravitational forces are small compared to the momentum transfer between the phases, both phases have nearly the same velocity. This is the case for phases with similar densities or for systems with very small particles.

Another description refers to the interactions during momentum transfer. If particles move with the continuous phase but do not significantly influence the flow field of this phase it is called a *one-way interaction*. Systems with one-

way interactions do not have to be modeled with multiphase approaches. The flow field is modeled with the single-phase equations and the volume fraction can be handled like a concentration. The term *two-way interaction* is used, if there is a relative velocity between the two phases which causes a reciprocal momentum transfer. If, in addition, the volume fraction of the disperse phase is so high that interactions between the particles and also between particles and walls have to be considered, one speaks of *four-way* interactions.

If in a multiphase system a disperse phase cannot be defined clearly because the extension of all phases is too large to neglect gradients of the transport values in them, the system is called a *discontinuous multiphase system*. The way to model such a system is to use the approaches for single-phase systems and additionally to describe the condition at the interface. This works well if the extent of each single-phase region covers a significant part of the total domain.

The conditions at the interface act as boundary conditions for the balances in both phases. Therefore, two conditions must be defined for each transport variable in each point. One is the equilibrium of fluxes, and the other is the relation between the values of the transport quantity. As neither momentum nor mass or energy can be accumulated at the interface, the fluxes must be equal on both sides. The ratio of the values depends on the quantity considered. As a result of the nonslip condition the tangential velocities are equal. Unless there is a significant mass transfer over the interface (e.g., melting or evaporation) this holds also for the normal velocity; otherwise source terms must be considered in the stress balance at the interface. Thermal equilibrium at the interface states that the interfacial temperature for both phases is the same. The distribution of chemical species is not equal in equilibrium but described by a distribution coefficient. Detailed explanations and equations for such systems can be found, e.g., in [18, 19].

Euler–Euler Method. The Euler–Euler method is used for modeling disperse systems. It utilizes continuous transport equations for each phase. These equations are based on single-phase equations but weighted with the volume fraction and appended with source terms describing the phase interaction [20].

For the equation of motion the interactions between phases are forces. In all systems with a relative velocity between the phases the drag force plays a major role. It is the main force which prevents a continuous increase in the relative velocity between the phases. Further forces which have to be considered depending on the properties of the phases are the virtual mass force, the Basset force, and other forces caused by different relative velocities at different points of the particle surface, such as the Saffman force and the Magnus force.

Mass and heat transfer between the phases determine the interaction terms in the concentration and temperature equations. For systems with a significant mass transfer over the interface it must be considered that heat and momentum are also transferred together with that mass.

The Euler–Euler approach is preferably used for systems with high volume fractions of the disperse phase or for relatively large particle sizes, because there are no formal restrictions for these properties. Models for the changes in turbulence caused by phase interaction are not well developed yet. Size distributions can be described only with a high numerical effort because most forces change as a function of the particle size, and therefore the size distribution must be divided into size classes, whereby each class is handled as an individual phase.

Euler–Lagrange Method. Alternatively, the Euler–Lagrange approach can be used for disperse systems. In this approach the continuous transport equations are also used for the continuous phase and extended by interaction terms. The disperse phase is modeled differently: particle parcels are defined and distributed in such a way that they represent the particle phase with its volume fraction and properties. For each of these parcels *Pi* the path and the velocities (convective and rotational) are determined by ordinary differential equations:

$$\begin{aligned} \frac{d\mathbf{x}_{Pi}}{dt} &= \mathbf{v}_{Pi} \\ m_{Pi}\frac{d\mathbf{v}_{Pi}}{dt} &= \sum \mathbf{F}_i \\ I_{Pi}\frac{d\boldsymbol{\omega}_{Pi}}{dt} &= \mathbf{T}_i \end{aligned} \tag{24}$$

where $\mathbf{x}_{Pi}$ is the position of the parcel, $\mathbf{v}_{Pi}$ and $\boldsymbol{\omega}_{Pi}$ are its convective and rotational velocity,

$\mathbf{F}_i$ the forces acting between the faces, I_{Pi} is the moment of inertia, and $\mathbf{T}_i$ the torque.

The velocity of the continuous phase and the particle phase are corrected in an iterative procedure considering interactions based on current particle paths. The particle parcels only give a statistical representation of the particle phase if their characteristics are averaged over a reasonable time interval. The time interval for averaging has no limits in the stationary case aside from giving statistically reliable results. For transient investigations the time interval of averaging determines the time resolution of the simulation. If statistical reliability is insufficient, the time steps of the particle simulation must be reduced.

The forces for phase interaction in the second of Equations 24 are the same as those mentioned for the Euler–Euler approach. Mass and energy transfer also have to be considered along the particle paths and statistically evaluated.

Consideration of the particle paths reduces the volume fraction and particle sizes which can be handled by this method. The volume of a parcel presents can not be larger than the smallest grid cell. For high volume fractions the danger of having more than one parcel in a cell at a time further restricts the volume ratio between a cell and a parcel. Reasonable results are therefore only obtained for very low volume fractions, usually in the range of 1%, exceptionally up to 5%. The numerical effort of the method increases with the volume fraction, because additional parcels have to be introduced.

On the other hand, this method provides better models of the influence of particles on turbulence than the Euler–Euler approach. Defining parcels with different properties allows one to model size distributions with only a small additional effort. A detailed description of the Euler–Lagrange method is given in [21, 22].

Grid Adaptation to Interface. The best way to model a discontinuous multiphase system is to define the reference system in such a way that the interface has a fixed position in space. In that case the grid can be constructed so that the interface is located at grid lines. The interfacial conditions can then be applied easily.

In most cases interfaces move, and the reference system cannot be defined as described above. In this case the location of the interface is a part of the solution of the model. To incorporate the interfacial conditions as with boundary conditions the grid can be adapted to the new location of the interface. As long as the dislocation is small, this affects only the cell layer close to the interface and the numerical error introduced is small. For large dislocations the cells near the interface would be deformed severely and it is necessary to add or delete cells. Detailed descriptions of adaptive methods are given in [23].

Volume of Fluid. If there is a strong movement of the interface, the grid adaptation method is numerically laborious and erroneous. An alternative is to locate the interface at an arbitrary position of the grid. Different methods act in this way (segment method [24], marker and cell method [25]). The most popular method is the volume of fluid method [26]. A volume fraction is defined and a transport equation is solved for it similarly to the Euler–Euler method. The volume fraction in most cells is either zero or one and the interface is located in the cells where the volume fraction lies between these values. The exact location of the interface is determined by the volume fraction in the cell. The direction of the interface is normal to the gradient of the volume fraction.

4. Numerics

4.1. Basics

In chapter 3 mathematical models for the description of transport processes in fluids have been introduced. Clearly, the coupled system of integrodifferential equations and algebraic equations can be solved analytically only for a very small number of limiting cases. For all practically relevant situations only a numerical, computer-based solution is possible.

The basic idea of a numerical solution is to replace the partial differential equation which is continuously defined over the range in space and time with a system of algebraic equations which gives the solution only at defined discrete points or for discrete intervals. For the finite difference method (FDM), values at single points are computed; for the finite volume method (FVM), characteristic values are determined, which are constant for a numerical cell; and for the finite

element method (FEM), parameters of a polynomial function over a cell yield the solution. All these are available for separate times. A completely different approach, used with the lattice Boltzmann method, is described separately.

As the solution of the algebraic equations, called the discretized equations, is fixed to certain points or elements in space and time, the discretization of space and time is the first step to be performed. Time is a one-dimensional coordinate, and so it can simply be split into intervals, i.e., time steps. The time step size can vary over the total time period considered. Stability and accuracy of the procedure on the one hand and computing time on the other depend on the time-step size chosen in relation to the space discretization (see Section 4.2).

The discretization of the three-dimensional space offers much more possibilities. The two discretization methods mainly used in CFD, FVM and FEM, require the subdivision of the total model space into non overlapping cells. In the ideal case the grids formed from these cells meet the following requirements:

- Geometrical requirements: The outer border of the grid should fit as closely as possible to the physical borders of the system to introduce the boundary conditions at the correct location. In the case of simple geometrical structures this is not a problem but it might become one for jagged structures. The more variable the cell shapes a CFD code accepts, the more easily such structures can be described without extensive refinement close to the boundaries.
- Physical requirements: To achieve sufficient accuracy in the solution the grid size should increase in areas of steep gradients and especially where they are varying. This criterion has the major problem that in can be fulfilled precisely only if the solution is known. In many cases general physical understanding of the flow investigated is sufficient to estimate where local grid refinement is necessary. In other situations preliminary computations on a rough grid give an orientation for grid improvements.
  The simulation of turbulent flows requires a few grid cell layers parallel to the boundary for an appropriate modeling of the laminar sublayer.
- Numerical requirements: The numerical requirements depend mainly on the numerical method used and the way it is implemented in the code. The crux of the matter is whether a structured grid is needed or an unstructured one is allowed. Especially for unstructured grids a wide variety of cell shapes can be imagined but not every one is supported by every code. Nearly all unstructured solvers can handle tetrahedral and hexahedral cells separately or in combination in one grid. In some cases more general formulations of polyhedral cells are available but are not standard.
  From a numerical point of view serious jumps in the size of adjacent grid cells should be avoided. Furthermore, cells should not tend to degenerate, that is, the ratio of volume to surface should not become too small.

In many cases very large numbers of cells would be needed to meet all requirements sufficiently. This might push the computational effort to an unrealistic level. Therefore, a reasonable compromise has to be found.

The major distinction of grid types is made between structured and unstructured ones. A structured grid is defined by three bands of grid faces, where the faces of one band do not intersect with each other but with the faces from the other bands. There is no restriction on the shape of the faces or the coordinate system in which they are defined. The cell shapes in structured grids are hexahedral, sometimes with one collapsed cell face. Structured grids have only restricted applicability to complex geometries but for simple geometries they can be generated easily.

In unstructured grids no global grid faces or lines are defined, but the domain may be divided in any way. This offers many more possibilities for grid fitting, but it normally cannot be done without an automated grid generator.

For some simulations it is necessary to perform grid adaptation in the course of the simulation. Reasons might be, e.g., moving boundaries (as in stirred vessels), movements of interfaces which have to be tracked, or strong transient changes in the solution which require local changes in refinement. If the new structure of the grid depends on the numerical solution, the numerical effort for the adaptation strategies is relatively high. Nevertheless, in many cases

with grid adaptation a significant improvement in accuracy and efficiency of a simulation can be gained.

Discretization of the model equations can be based on the discretization of space and time. The different methods that are available vary in their mathematical approach and range of application. An insight is given here for two methods: the finite volume method, and the lattice Boltzmann method, with stress on the forme.

A third widespread method is the finite element method. It is extensively explained in → Mathematics in Chemical Engineering, Chap. 7.6 and therefore not discussed here.

4.2. Finite Volume Method

Historically, the most common numerical method in CFD is the finite volume method (FVM). It is also used by the presently most widest distributed commercial CFD codes FLUENT, CFX, and Star-CD. Its success in CFD is related to physical equivalents in the approach.

The fundamental concept is the consideration of grid cells (also called *control volumes*) in which all physical parameters and system characteristics are assumed to be constant. The balance equations are integrated over each of this cells. For volume sources these integrals can be solved directly by considering these sources as constant over the cell. The volume integrals of the transport terms are transformed into surface integrals by using the theorem of Gauss. As the physical properties are constant within each cell, they can also considered to be constant along each cell face, which permits the surface integral to be resolved. The value or the derivative of the solution at the cell face is contained in the expressions gained. While the values are constant within each cell, they jump unsteadily at the cell faces, and the values and derivatives at the faces have to be expressed by the values in the cells, which are fixed at certain reference points, i.e., the nodes.

This approach is, in general terms, the reverse of the derivation of the transport equations, where a finite model volume is considered initially and fluxes over the boundaries and volume sources are balanced. In the second step the limiting expression for the model volume approaching zero is determined. This analogy reveals another advantage of the method in a physical sense: as the surface integral of the transport terms expresses the fluxes over the cell surface, a numerical error in the determination of these fluxes does not violate the integral conservation of the balanced property. The laws of conservation of mass, momentum, and energy are the fundamentals of modeling for CFD, and therefore a method upholding these laws inherently has been most widely accepted by engineers.

Nowadays, this advantage of FVM is no longer significant, firstly, because the accuracy of all methods has been increased, so that for well-designed grids the error in the computation of fluxes is small compared to other errors in the course of simulations, and, secondly, because advanced grid techniques, like certain types of unstructured grids or sliding grids, do not uphold this advantage exactly. Nevertheless, it is still the most widely distributed CFD method and is therefore described here as an example. More details can be found, e.g., in [27 – 29].

Discretization in Space. We first consider the general shape of a transport equation for the quantity ϕ. For purposes of simplicity only the two-dimensional version is used, but the extension to three dimensions is straightforward. Discretization in time as discussed later, so we consider here the stationary form. The velocity field is assumed to be known as well as the molecular transport coefficient Γ, which might vary in a known way over the analyzed space.

$$0 = -v_x \frac{\partial \phi}{\partial x} - v_y \frac{\partial \phi}{\partial y} + \frac{\partial}{\partial x}\left(\Gamma \frac{\partial \phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(\Gamma \frac{\partial \phi}{\partial y}\right) + S_\phi \tag{25}$$

For reasons of simplicity the integration is shown here for an equidistantly structured grid. But there is no general restriction — finite volume discretization can also be carried out for nonequidistant and unstructured grids. Note that in the two-dimensional case the "volume" for integration is a face and the "volume surface" is a line.

For the grid the compass notation shown in Figure 5 is normally used [27]. The nodes are marked with capital letters, *P* being that of the cell considered. The points at cell faces are marked by lower-case letters. The final linear equation system can contain only values with

Figure 5. Nomenclature in a two-dimensional grid for finite volume method

capital letter indices, values with lower case indices are not defined and must be replaced by the former.

Integration of Equation 25 over the control volume gives

$$0 = -\int_V v_x \frac{\partial \phi}{\partial x} dV - \int_V v_y \frac{\partial \phi}{\partial y} dV + \int_V \frac{\partial}{\partial x}\left(\Gamma \frac{\partial \phi}{\partial x}\right) dV + \int_V \frac{\partial}{\partial y}\left(\Gamma \frac{\partial \phi}{\partial y}\right) dV + \int_V S_\phi dV \tag{26}$$

Conversion of volume integrals of the transport terms and resolution lead to:

$$0 = -\int_A \mathbf{n} v_x \phi dA - \int_A \mathbf{n} v_y \phi dA + \int_A \mathbf{n}\left(\Gamma \frac{\partial \phi}{\partial x}\right) dA + \int_A \mathbf{n}\left(\Gamma \frac{\partial \phi}{\partial y}\right) dA + \int_V S_\phi dV$$

$$0 = -(v_x A\phi)_e + (v_x A\phi)_w - (v_y A\phi)_n + (v_y A\phi)_s + \left(\Gamma A \frac{\partial \phi}{\partial x}\right)_e - \left(\Gamma A \frac{\partial \phi}{\partial x}\right)_w + \left(\Gamma A \frac{\partial \phi}{\partial y}\right)_n - \left(\Gamma A \frac{\partial \phi}{\partial y}\right)_s \overline{S} V \tag{27}$$

A_e, A_w, A_n and A_s are the cell faces crossing e, w, n and s and **n** is the face normal.

Finally, the values and the derivatives of ϕ at the cell faces must be replaced as a function of the values at the nodes. The derivatives are approximated by using the central difference, which is accurate to the second order, e.g.

$$\left(\Gamma A \frac{\partial \phi}{\partial x}\right)_w = \Gamma_w A_w \left(\frac{\phi_P - \phi_W}{\delta x_{WP}}\right) \tag{28}$$

where δx_wp is the distance between the points W and P.

To express the values of ϕ various approaches are used which differ in their stability and accuracy. Most of them are asymmetric and depend therefore on the flow direction. We discuss them for cell face w and a velocity $\nu_{\mathrm{x,w}}$ from W to P.

- *Upwind Differencing Scheme (UD)*

$$\phi_w = \phi_W \tag{29}$$

This scheme is unconditionally stable, but it is only accurate for the first order. It is the only scheme which does not produce any overshots or undershots without additional limiters and therefore guarantees the solution to be in the physically meaningful range (no negative concentrations, etc.). On the other hand, the numerical error is relatively large. It has the effect of smoothing strong changes in the gradients—a property called *numerical diffusion*. The error can be minimized if the local velocity vector is nearly parallel to the face normal vector.

- *Central Differencing Scheme (CD)*

$$\phi_w = \frac{\delta x_{Ww}\phi_W + \delta x_{wP}\phi_P}{\delta x_{WP}} \tag{30}$$

This scheme is only conditionally stable but it is second-order. Central schemes normally give a better approximation of steep slopes, but they show significant nonphysical oscillations of the solution. In the worst case these oscillations can build up and lead to a diverging solution. CD schemes are stable and advisable for diffusion-dominated processes.

- *Quadratic Upstream Interpolation for Convective Kinetics (QUICK)*

$$\phi_w = -\frac{1}{8}\phi_{WW} + \frac{6}{8}\phi_W + \frac{3}{8}\phi_P \tag{31}$$

QUICK is the basis for most third-order schemes used today. With a combination of central and upwind aspects it joints properties of both schemes discuss above. Oscillations occur, but to a lesser extent than with the CD scheme. QUICK has a much wider range of stability than CD but restrictions remain for systems without significant diffusion terms. To improve this third-order scheme various advancements have been developed. The main advantage is gained from the combination with so-called *limiters*. Limiters are extensions of the numerical scheme which prevent the formation and pronunciation of local extrema but keep the numerical accuracy of a scheme.

For the source term a linear approach in ϕ is used:

$$\overline{S}V = S_0 + S_1\phi \tag{32}$$

Discretization in Time.

For transient cases a time derivative of the transport quantity also occurs in the equation. If the two-dimensional Equation 25 is extended in this way one obtains:

$$\frac{\partial\phi}{\partial t} = -v_x\frac{\partial\phi}{\partial x} - v_y\frac{\partial\phi}{\partial y} + \frac{\partial}{\partial x}\left(\Gamma\frac{\partial\phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(\Gamma\frac{\partial\phi}{\partial y}\right) + S_\phi \tag{33}$$

The philosophy for the time discretization is the same as for the discretization in space: The equation is integrated over the grid cell as well as over the time interval. The integration of the left-hand side can be performed easily:

$$\int_V\int_t^{t+\Delta t}\frac{\partial\phi}{\partial t}dtdV = V(\phi_P^{t+\Delta t} - \phi_P^t) \tag{34}$$

For the time integral of the right-hand side a linear relation to the values of ϕ at the old and the new time step is assumed:

$$\int_t^{t+\Delta t}\phi dt = \left[f\phi^{t+\Delta t} + (1-f)\phi^t\right]\Delta t \tag{35}$$

where f is a weighting factor between zero and one. For a space discretization which needs only the values of ϕ in P and its direct neighbor points the discretized equation reads:

$$\begin{aligned} a_P^{t+\Delta t}\phi_P^{t+\Delta t} = {} & a_E\left[f\phi_E^{t+\Delta t} + (1-f)\phi_E^t\right] + \\ & + a_W\left[f\phi_W^{t+\Delta t} + (1-f)\phi_W^t\right] \\ & + a_N\left[f\phi_N^{t+\Delta t} + (1-f)\phi_N^t\right] + \\ & + a_S\left[f\phi_S^{t+\Delta t} + (1-f)\phi_S^t\right] + \\ & + a_P^t\phi_P^t \end{aligned} \tag{36}$$

in which the coefficients $a_{\mathrm{P}}^{t+\Delta t}$ and a_{P}^t depend on f linearly, and a_{i} are the coefficients resulting from space discretization and from Equation 34.

For different values of f different methods can be derived. The most common ones are shown in Figure 6 .

- *f=0 (explicit method)*
This method is numerically simple to use because only independent linear equations are derived. It is of first-order accuracy. On the other hand, it is only conditionally stable. For applications in which the flux is dominated by the convective part (and this is the major part of all CFD applications) the *Courant–Friedrich–Lewy criterion* determines the stability range:

$$1 \geq C_\Delta = \frac{|\mathbf{v}|\,\Delta t}{\Delta x} \tag{37}$$

C_Δ is the so-called *Courant number*.

- *f=1 (implicit method)*
This method is unconditionally stable and also first-order accurate. If a final state of a process is more interesting than the transient behavior, this method can be used with relatively large time steps.

Figure 6. Discretization in time – coupling of values according to different methods
a) Explicit; b) Implicit; c) Crank-Nicolson

- *f=0.5 (Crank–Nicolson method)*
  This method is second-order accurate. It is conditionally stable but larger Courant numbers than in the explicit method can be handled. It is used if a high accuracy in time is required.

4.3. Pressure Correction Methods

One of the crucial points of fluid dynamic modeling are the nonlinearities in the equation of motion and the lack of an explicit pressure equation for incompressible flow. This was outlined in connection with the equation of motion.

There are different approaches to deal with this problem. The directly coupled solution of the equation of motion and the equation of continuity is possible, but is mathematically unstable, especially for the finite volume method, and is seldom used. Also, the approach of an artificial compressibility is only successful and efficient in a few cases.

The most commonly used alternatives are pressure correction schemes. They break up the velocity and pressure into an estimated value and a corrective part. Starting with an estimated pressure field, they compute an estimated velocity field, or vice versa, using the equation of motion. For the velocities in front of the derivatives in the convective terms (see Equation 6) estimates are used. Reorganization of the discretized momentum balance gives an equation for the pressure correction as a function of velocity correction. With the help of this equation the discretized continuity equation can be transformed into a pressure correction equation. Iterative solution of all these equations lead to a stepwise approach of velocity and pressure. It is important to update the "parameter velocity" in the convective term and other dependent parameters in each iterative cycle. If necessary, coupled equations (e.g., turbulence models) must be solved at the end of each step.

One of the most basic pressure correction algorithms is the SIMPLE algorithm [27]. Because it does not converge stably, a significant under-relaxation has to be used. Reversed algorithms have been developed since then, but the underlying basic principles are the same.

4.4. Lattice Boltzmann Method

The lattice Boltzmann method (LBM) differs greatly from FVM because it is not a discretization of the transport equations but a statistical method which gives an average result for the solution of the equations. To provide sufficient statistics the method requires a relatively fine grid and small time steps, but it performs much faster on a fine grid than FVM does on the same grid. The grid used is completely regularly structured, but the location of wall boundaries is not restricted to the grid lines. Therefore, the method is suited for geometries with sophisticated wall shapes like porous media. While some years ago the grid requirements caused an impassable numerical effort, such a method can be handled today on parallel computers. It is especially suited for simulations which require a fine grid to handle the models, like large-eddy simulations of turbulent flows.

For lattice Boltzmann simulations a number of numerical particles with properties like velocity, temperature, and concentration are dis-

tributed over the grid in such a way that averaging of their properties gives the initial conditions of the flow. The simulation consists of a first step in which the particles move due to their individual velocities. In a second step collisions between particles and also between particles and walls are interpreted according to collision rules. The collision rules describe the change in the properties of each of the particles in the collision. They must be formulated in such a way that they cause statistical changes so that the averaged property field fulfills the transport equations. [30, 31]

As the method is still relatively new, not all models can be used yet, but the current development is rapid.

5. Interpretation

As mentioned in Chapter 2, the volume of computed data of a CFD simulation is too large to interpret the numbers directly. In a graphic visualization the data are much easier to comprehend.

A basic step of a suitable visualization is an appropriate reduction of the data. Three-dimensional transient data cannot be visualized at once, and the visualization of the velocity vector field can not be realized effectively in a two-dimensional plane. But not all aspects of the data field are relevant to answering the initial question. Relevant data, however, can be extracted, and data can be averaged or combined to derive meaningful results. To transfer information into a graphical presentation requires that the figure be clearly readable and quantitative. Aspects of data reduction (location of a slice, chosen velocity components) have to be marked, and a legend must be given which allows quantitative interpretation of colored figures.

Visualization is not only useful for finding the result of the simulation. It also helps to detect errors. For this purpose the whole data field should at least be scanned roughly. As the aim of this procedure is to find irregularities in the solution, the layout of the presentation is of minor interest, but a quantitative interpretation of the data must be possible.

To judge the results all errors of the simulation must be analyzed as well as possible and quantified. The main categories are:

- *Modeling errors* refer to the differences between the values of all quantities in a real physical system and the values resulting from an exact solution of the mathematical model. Not all physical relations can be reproduced exactly in a mathematical formulation. Furthermore, not all mathematical models can be solved numerically with reasonable effort. Therefore, additional assumptions and restrictions are introduced which increase the modeling error. Examples are the application of turbulence models, the neglect of temperature dependencies of parameters or simplified approaches for boundary conditions.
  A quantitative estimate of the modeling errors is very difficult. If the mathematical model can be solved analytically (at least for a limiting case) and the corresponding quantities can be measured, a direct comparison is possible. Even in this case the measurement error from the experiment must be considered. In most cases such a direct comparison is not possible and one is restricted to experience from similar cases or to comparison of different model approaches for the same situation.
- *Discretization errors* refer to the difference between the solution of the continuous mathematical model and the discretized equations. The discrete solution is computed only for the nodes (which are representative for a certain volume according to FVM) and for time steps. For the locations between these points in space and time only approximations based on the values at the nodes can be used.
  The solution of the discrete equations at the nodes differs from the solution of the continuous equations at the same points. This is caused by the assumptions and approaches used in the course of discretization. While this is valid for all discretization schemes, it can be most easily explained for the finite difference method (FDM) (see → Mathematics in Chemical Engineering, Chap. 7.3 or [32]).
  According to this method, the approximation is derived from the Taylor series where only the first terms are considered. The neglected terms give the discretization error. The procedure is based on the assumption that the following terms in the Taylor series are decreasing. Therefore, the discretization error can be approximated by the first neglected term. This

term is proportional to the grid size with a certain power. This power is the so-called *order of accuracy*. The more terms considered the higher the order of the scheme. The order of a scheme is also used for other discretization methods. It states by which power the discretization error is reduced in relation to the reduction of the grid size. This means that a scheme of higher order is not always more accurate than a scheme of lower order if the schemes are derived in completely different manners. But the influence of grid size reduction is greater for the scheme of higher order.

- *Truncation of iterative procedures*: Iterative procedures are used on different levels for the solution of the discrete equations. Normally the linear algebraic equation systems are solved iteratively. Also, the coupling between the equations is often handled iteratively. The most important example of this are the pressure correction schemes (see Section 4.3). Iterative procedures approach the solution asymptotically. They are terminated if a certain accuracy is reached. Criterion for termination is the residual. It can be defined in two different ways. The first alternative is the difference in the solution between two iterations. This value is easily determined, but it is dangerous, because for slow convergence the differences between two iterations is small, even far away from the solution. The second alternative can be used if the problem can be formulated as:

$$\mathbf{F}(\mathbf{x}) = 0 \tag{38}$$

The residual of the nth iteration $\mathbf{r}^n$ is then defined as:

$$\mathbf{F}(\mathbf{x}^n) = \mathbf{r}^n \tag{39}$$

Both definitions of the residual give values for each node. For a truncation criterion different statistical methods are used to derive a characteristic value. This can be either the maximum, the average, or a weighted average of the value itself or of a normalized value.

- *Representation errors*: In the computer all numbers are represented by a limited number of digits. This might result in significant errors, e.g., if a small difference of large numbers is computed. Normally, this type of error is of minor importance in CFD simulations.

The different types of errors are usually additive. Therefore, it does not help to improve the accuracy of one aspect if the error in this regard is smaller than other errors. In most cases for simulation the limiting factor for error reduction is the modeling error. All other errors are usually small by comparison. A quantitative judgment has a higher priority than indifferent formulations such as "grid independence".

6. Industrial Application

CFD is a tool of increasing importance in industrial applications. The expertise of industrial users is mainly in the field of fluid dynamics or chemical engineering, not in numerics or programming. Therefore, industrial problems are solved with commercial codes which are available at high level with regard to modeling and numerics. Furthermore, such codes have a user-friendly interface and support which allows even inexperienced users to obtain first results quite fast. Commercial codes are continuously being developed and achieve more or less the state of the art. Nevertheless, the different codes are specialized in different fields of applications and therefore it is necessary to check the available models before a new kind of application is tackled. Often additional models can be implemented by user coding, but the effort required to do so is great and it should be checked before beginning whether another code provides a better foundation for the case considered.

To illustrate different modeling requirements, some examples for applications in chemical engineering are presented. This cannot give a complete overview of the most current usage of CFD in chemical engineering but gives an impression of the variety of applications.

- Tubular reactor: Tubes without internals have a simple geometric structure. They are a part of nearly all technical apparatuses as inlet and outlet pipes and in some cases they are used as reactors. Problems in modeling occur due to the large ratio between length and diameter, which requires a compromise in meshing between number of cells and shape of cells. In some cases the number of cells can be reduced by utilizing symmetry properties of the system.

Tubular reactors are often used to mix non-Newtonian fluids or, in a jet configuration, to mix Newtonian fluids very fast down to microscopic levels. For non-Newtonian fluids, e.g., in polymerization processes, chaotic mixers [33] consisting of tubular loops or static mixers [34, 35] within the tubes are used. In both cases the geometry of the flow becomes much more complicated. Especially for static mixers sufficient flexibility is only provided by unstructured grids.

In jet flows the modeling of turbulence is of great importance. As tubular reactors are relatively narrow, wall effects have a significant influence on the flow. Therefore, in most cases special wall models have to be used, and this increases the modeling and numerical effort. Furthermore, turbulence in tubes is often nonisotropic. This reduces the applicability of RANS simulations.

- Stirred vessel: Stirred vessels are widely used in chemical engineering for single phase and multiphase flows. The flow field is markedly inhomogeneous and transient. Characteristic of all stirred vessel configurations is the combination of static and moving elements. In the simplest case the static parts are rotationally symmetric. Then they can be modeled as a moving wall in a rotating reference frame [36]. If there are baffles, the rotational symmetry is broken and extended approaches are used. A good overview on these approaches is given by in [37]. If only the stationary solution averaged over a large number of stirrer revolutions is at interest, the power input from the stirrer can be included in source terms. This system can be solved for the stationary case on a fixed grid. For more detailed simulations the grid is divided in two overlapping or nonoverlapping parts. One of them moves with the stirrer; the other is static. As the stirrer motion has to be resolved sufficiently in time, only small time steps can be used, and the simulation becomes relatively extensive.

  RANS simulations often do not give a sufficient description, especially in presence of chemical reactions, because the flow field is inhomogeneous. As the fine resolution required for large-eddy simulations is numerically extensive, a remedy is to apply the lattice Boltzmann method [38].
- Precipitation reactor: Precipitation is usually simulated to predict the particle size distribution in the system [39, 40]. The initial supersaturation in precipitation processes is high, and therefore nucleation and particle growth start at a high rate. This requires appropriate turbulence modeling, including micromixing models [41]. The particles are very small, so only one-way coupling is relevant and the simulation can be carried out as pseudo-single phase. On the other hand, the solution of the population balance must be integrated into the simulation [15].
- Bubble column: Bubble columns are a typical example for two-phase flows. The difference in density between gas and liquid causes a relevant relative velocity between the phases. Depending on bubble size and volume fraction, either Euler–Euler [42, 43] or Euler–Lagrange [44, 45] approaches are used. In most practical applications the requirements for the Lagrangian approach are not met because the volume fraction is too high. But to describe the nonuniform bubble size population, balances have to be solved. This is much easier in connection with the Lagrangian approach than with the Eulerian approach.
- Membrane module: A newer apparatus used in chemical engineering is the membrane module. Its numerical simulation is at the very beginning because of the variety of aspects which have to be considered. These are, for instance:

  Presently the modeling approaches do not consider all of these aspects. The main stress is on modeling the two flow regions divided by the porous membrane under certain pressure conditions [46, 47].
  - Flow through a porous medium
  - Coupling of two flow regions
  - Multiphase flow
  - Non-Newtonian fluids
  - Fouling

It is obvious from this listing that the qualified application of CFD can not be performed without well-founded knowledge of applicable models and some insight into the numerical procedures.

The development of refined products like fine chemicals and active agents will be of growing importance in the chemical industry, and CFD

will play an important part in the design of the necessary apparatus. This requires the consideration of parallel and consecutive chemical reactions of different rates and simulations of multiphase systems including the prediction of particle size distributions. Consequently, emphasis in CFD development for this field will be on models and solution methods for fine spatial and temporal resolution and for a detailed description of the physics.

The advances in CFD interact strongly with hardware development. On the one hand the available computing power determines which mathematical models and which numerical methods can be used with reasonable numerical effort, and on the other it affects the direction of development of new models and methods. Due to the fast pace at which new powerful computer hardware evolves and becomes available, model development does not restrict itself to quantitative refinement but regularly includes new fields of research. More recent improvements are large-eddy simulations of turbulent flows instead of Reynolds-averaged approaches, and models for multiphase systems. A newer trend in the field of numerical methods is the application of the lattice Boltzmann method. Further innovations can be expected.

1. Introduction

More than a century ago LUDWIG BOLTZMANN (1844–1906) elaborated a procedure allowing the macroscopic properties of matter to be linked with the molecular details and interactions of its constituent particles. This approach is known today as statistical thermodynamics or, more generally, as statistical mechanics. However, up to the arrival of sufficiently cheap and accessible numerical computers in the last third of the twentieth century, practical results could be obtained only for the simplest systems, in some limiting cases, or under drastic assumptions. This has proven intellectually challenging and has yielded many insights, but the urge has remained to overcome the simplifications and to look at specific systems of interest in various disciplines such as physics, chemistry, biology, geoscience, and engineering. The limitations have been pushed back in the last few decades, and many systems can now be investigated by following Boltzmann's principles. Nevertheless, it is still impossible to carry out this method for any real system of even the smallest macroscopic size. Approximations, although much weaker than before, must still be made, and the task remains daunting in many cases.

The computational methods used today to follow Boltzmann's lead, i.e., to cross the bridge between the microscopic, molecular world and the macroscopic observables measured in the laboratory, are known as molecular simulations. They come in many variants, the two major families of which are Monte-Carlo (MC) simulations [1] and the molecular dynamics (MD) simulations. The basic idea underlying all molecular simulations is simple and follows directly from Boltzmann's considerations: Construct a sufficient number of microscopic configurations, or states, compatible with (1) knowledge about the intermolecular (or interatomic) interactions in the system and (2) the macroscopic thermodynamic constraints (temperature, density, etc.) of the system under consideration. This could be called the “Gallup poll” [2] approach to the

thermodynamic ensemble: Since this powerful abstract notion upon which the Boltzmann approach rests cannot be practically realized, one must be satisfied with a representative sample. Like in the polls, the trouble lies, of course, in the representativeness. However, once the sample has been constructed, it can be used to do statistics, i.e. to compute average values of quantities that can be calculated from the configurations in these samples.

Example 1. Assume that the positions of all atoms in a sufficiently large sample of water are known over a sufficient length of time under the external constraints (e.g., at a given total energy, temperature, or . . .) imposed on the system. We want to know the thermodynamic average of all distances between neighboring pairs of oxygen atoms, d_{O-O}, under these conditions. Since the positions of the atoms have been constructed by means of the simulation so as to be compatible with the external conditions, and there are enough of them, according to Boltzmann the thermodynamic average, denoted here $\langle d_{O-O} \rangle$, is simply the usual average over all values d_{O-O} computed from the atomic positions in the simulated system. If a total of M such values d^i_{O-O} can be computed from the configurations, Equation (1) applies.

$$\langle d_{O-O} \rangle = \frac{1}{M} \sum_i^M d^i_{O-O} \tag{1}$$

2. Fundamental Approximations

At the energies relevant for most of biology, chemistry, and engineering, matter can be considered as consisting of molecules which can undergo changes (chemical reactions). The molecules themselves consist of atoms, which in turn consist of nuclei and electrons. Such particles of molecular, atomic, or subatomic dimensions are, in principle, subject to quantum mechanics, as expressed, e.g., through the Schrödinger equation for the wavefunction, rather than to classical mechanics, i.e., the Newton equation of motion. In most cases of interest here, however, approximations can be used to simplify the problem. In the Born – Oppenheimer approximation [3], it is recognized that the mass of the electrons is much smaller than the mass of the nuclei. The problem concerning the electrons and that concerning the nuclei can thus be treated separately. The energies holding together the atoms to form molecules as well as the energies holding together molecules, e.g., in liquids or solids, can thus be computed by solving quantum mechanical Schrödinger equations only for the electrons. It is one of the main purposes of quantum chemistry to devise methods, usually numerical, to tackle this complex problem for molecular or supramolecular systems [3-5]. Unfortunately, even with the largest computers available in the foreseeable future, it will not be possible to elaborate these energies for extended systems consisting of large disordered assemblies of molecules. Yet, according to what has been said above, in order to do statistical mechanics, as many molecular arrangements as possible compatible with a given set of constraints must be constructed, and to do this, the energies are needed.

The interaction energies between particles (individual atoms, atoms in molecules, groups of atoms, molecules themselves), which can be obtained, in principle, from the solution of the Schrödinger equations for the electrons, can then be expressed as potential functions, or potentials. They are usually written as functions of the positions (and, if needed, orientations) of the particles. Simplifying assumptions as to the mathematical form of these potentials are introduced at this level (see Chap. Interaction Models).

The second major approximation is that classical dynamics is used for the nuclei themselves, i.e., the atoms and molecules, rather than quantum mechanics, to construct the ensemble of configurations. The heavier the masses involved, the weaker the interactions, and the higher the temperature, the better this approximation will be. Equivalently, the smaller the so-called thermal De Broglie wavelength $\Lambda = \sqrt{\frac{h^2}{2\pi m k_B T}}$ associated with a particle of mass m at temperature T compared to a characteristic length (in a gas, e.g., on the order of the mean free path), the better the classical approximation [6]. At room temperature, the classical dynamics become a limitation only for the lightest atoms (e.g. hydrogen, helium) when they are strongly bonded.

Before we proceed we should note here that in selected cases, essentially for small systems for which not too large a number of configurations is sufficient, the quantum mechanical problem for the electrons can be solved (usually in a simplified approach) simultaneously with the generation of the configurations. Thus, no explicit interaction model must be specified, although the quantum mechanical calculations usually involve a number of adjustable quantities which are empirically chosen. One popular approach is Car – Parrinello MD (CPMD) [7]. Here, electrons belonging to all particles present in the system are treated, in the density-functional theory (DFT) approach, through equations of motion. This method is not free of arbitrariness, e.g., in the choice of the so-called functional; it is extremely CPU-intensive and is thus restricted to very small systems (a few tens of small molecules) which can be explored in a short time (a few picoseconds). In other approaches, the quantum mechanical equations are retained only for a small part of the system, while the larger part is described classically. The system is usually divided up geometrically into a smaller region which is treated quantum mechanically (by the ab initio, DFT, or, mostly, semi-empirical approach) and a larger one in which the interactions are described by an interaction model (force field). Coupling these two regions together is problematic and again involves choices and approximations. These so-called quantum-classical simulations are mostly outside the scope of this article, but we stress that if systems with real chemical reactions are to be studied approaches like the ones sketched here must be used.

Besides the two fundamental approximations (classical mechanics and interactions via potentials), several more are needed in order to study most systems of interest, mainly in two areas: The way the interactions are described, and the approximations needed to mimic extended systems with finite computational resources. The following sections are devoted to these aspects. In the generally available simulation packages (freeware, shareware, commercial) these approximations are often dealt with in a way somewhat hidden from the user. It is not the purpose of this article to evaluate the various approaches proposed in these packages and to give recommendations. We believe, however, that users of such software should be aware of the approximations involved and of their consequences: All results should always be

critically evaluated in the light of the approximations made.

[Top of Page]

3. Interaction Models

The interaction model, often called force field, is, beyond all further “technical” approximations to be discussed below, the crucial input to a classical MD simulation. Within the restrictions in time and space inherent to the technique, the simulation is supposed to yield the “exact” results associated with a given interaction model. In other words, failure of the simulation to reproduce a given observable in a given system should be ultimately ascribable to deficiencies in the interaction model.

Two different philosophies can be distinguished: In the first, MD simulations are used to explore systematically the statistical mechanics of certain types of interaction models, usually highly idealized simple ones (e.g., hard spheres or Lennard–Jones spheres [8], see Eq. 7). Such simulations thus yield in some sense the “exact” result for the idealized model. The second approach attempts to reproduce as precisely as possible the properties of specific chemical systems. Water has been, for obvious reasons, a frequent target of such studies [9]. In the latter case, it is a reasonable and efficient approximation to write the total potential energy of a molecular system U^{total} as a sum of terms (Eq. 2)

$$U^{\text{total}} = \sum_{\text{all moleculle}} U^{(1)} + \sum_{\text{all pairs of molecules}} U^{(2)} + \sum_{\text{all triples of molecules}} U^{(3)} + \cdots \tag{2}$$

where $U^{(1)}$ is an energy associated with a single molecule, e.g., its intramolecular energy (see below) or its energy in an external field. For small molecules, this term is often nearly constant and thus omitted in the simulations. $U^{(2)}$ is the interaction energy between pairs of molecules. In most cases, only terms of this type are used in the simulations. $U^{(3)}$ is an additional interaction energy that depends simultaneously on (e.g., the positions of) three molecules. Figure 1 illustrates the second and third terms of this series of approximations.

Figure 1. Left: Interaction $U^{(2)}$ (solid lines) between two molecules represented as circles. Middle: Interactions $U^{(2)}$ between three molecules; the total energy is the sum of the three $U^{(2)}$ terms, each of which is the same as in the two-body case, i.e., each interaction is deemed to be independent of the presence or absence of the third molecule. Right: Interactions between three molecules as the sum of the two-body terms $U^{(2)}$ plus a modifying three-body term $U^{(3)}$ (dashed circle).

In a system of N molecules, there are N terms of the first kind; the number of terms of the second kind increases as $N(N–1)/2 \propto N^2$, and the number of terms of the third kind increases proportionally to $N(N–1)(N–2)/6 \propto N^3$. Even though not all terms need to be evaluated, these proportionalities govern the amount of computer time needed to evaluate the interactions in a simulation.

3.1. Intramolecular Interactions

Intramolecular interactions are usually stronger than intermolecular interactions. If this is the case, the molecular geometry can be assumed not to change much when a molecule interacts with its neighbors. Since the intramolecular energy will then be constant, it can be neglected, even though it may be large: A rigid body is then a suitable molecular model. This works in some instances for small molecules. In many cases, however, and in particular for large molecules, the energetics involved with changes in the molecular geometry must be included in the simulation. Since it is chemically intuitive, the intramolecular energy is often expressed as a power series in internal displacement coordinates ρ [10] (Eq. 3).

$$\begin{aligned} U^{(1)} &= \sum_{\text{all pairs}(l,m)\text{of coordinates}} k_{lm} \cdot \rho_l \cdot \rho_m + \sum_{\text{all triples}(l,m,n)\text{of coordinates}} k_{lmn} \cdot \rho_l \cdot \rho_m \cdot \rho_n \\ &+ \sum_{\text{all quadruples}(l,m,n,o)\text{of coordinates}} k_{lmno} \cdot \rho_l \cdot \rho_m \cdot \rho_n \cdot \rho_o + \cdots \end{aligned} \tag{3}$$

Examples of such internal displacement coordinates are the bond stretch $\rho = r_{ij} – r_{ij}^0$, where r_{ij} denotes the module of the distance between two atoms in a molecule and r_{ij}^0 its equilibrium value, and the angle bend $\rho = \alpha_{ijk} – \alpha_{ijk}^0$, where α_{ijk} denotes the angle spanned by particles i and k at the position of particle j. The constants k_{lm} are called the force constants; their definition in the literature varies due to the inclusion or omission of the factor of 1/2 originating from the definition of the power series. The same holds for the higher constants k_{lmn} and k_{lmno}. Note that this definition of $U^{(1)}$ rests upon the notion of equilibrium geometry, i.e., it is suitable for molecules for which only one conformer must be considered.

In the first term of Equation (3), the terms with $\rho_l = \rho_m$ are called diagonal terms. Nondiagonal terms ($l \neq m$) are usually included only if the corresponding coordinates ρ_l, ρ_m share a common particle (i or j). The higher terms in Equation (3), usually called (mechanical) anharmonicities, are also not frequently used. In some cases, however, they cannot be omitted since they play an important role in the redistribution of energy in the system. Another frequently used approximation for anharmonic intramolecular bond stretches is the Morse potential (Eq. 4) [11]

$$U^{\text{Morse}}(r_{ij}) = D \cdot \left(1 - e^{-a\left(r_{ij} - r_{ij}^{o}\right)}\right)^2 \tag{4}$$

where D is the depth of the potential well, and a a constant.

We note again that the number of operations needed in a simulation to evaluate Equation (3) is proportional to *N*, the number of molecules. Thus, the computational weight of these terms is usually not very large, in contrast to the intermolecular terms (see Section Intermolecular Interactions). More details about the modeling of intramolecular interactions, e.g., further definitions of internal coordinates, information on the quantum mechanical background, and potential functions suitable for molecules with several conformers can be found in ⟶ Molecular Modeling.

3.2. Intermolecular Interactions

3.2.1. *Pair Potentials*

In most cases the intermolecular interactions are expressed in terms of potentials of type $U^{(2)}$ only (see Eq. 2). A frequently used approach consists of writing this interaction potential as a sum of so-called site–site pair potentials (Eq. 5)

$$U^{(2)} = \sum_{\substack{\text{all sites } i \\ \text{on molecule } \alpha}} \sum_{\substack{\text{all sites } j \\ \text{on molecule } \beta}} U_{ij}(r_{ij}) \tag{5}$$

In many instances, “site” is identified with “atom position”, but if molecules are described as rigid entities, other points on the molecular frame can be used as sites. Examples of such site–site pair potentials are the electrostatic (Coulomb) interaction between two partial electric charges *q* (Eq. 6)

$$U^{\text{Coulomb}}(r_{ij}) = C \cdot \frac{q_i \cdot q_j}{r_{ij}} \tag{6}$$

where *C* is a constant depending on the energy unit used. We note already here that special techniques such as Ewald summations or reaction field techniques [12], which are computationally expensive, must be used to evaluate Coulomb terms in the periodic arrangements that are mostly used to represent extended systems. This is due to the long range ($U \propto r^{-1}$) of this interaction.

Shorter range repulsive and attractive (van der Waals-type) interactions are often approximated by the Lennard–Jones (LJ or 12-6) potential, which contains two constants ε and σ (or *A* and *B*; Eq. 7).

$$U^{\text{Lennard-Jones}}(r_{ij}) = 4 \cdot \varepsilon_{ij} \cdot \left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6} \right] = \frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^{6}} \tag{7}$$

The constants ε and σ used in the first notation represent the depth of the potential well and the value of the argument *r* for which $U^{\text{Lennard–Jones}} = 0$, respectively. As an illustration of the typical order of magnitude for the two interaction types mentioned above, Figure 2 shows a Lennard–Jones potential and a Coulomb potential between two small partial charges of opposite sign, typical for those on nonpolar molecular groups. The examples given below will show that about ten times higher partial charges are used to represent polar groups, and even higher ones for ions.

Figure 2. Typical interaction potentials as a function of distance. Lennard–Jones (LJ) potential between two methane (CH_4) molecules carrying one site each (ε/k_B = 148.6 K, σ = 3.728 Å, 1 Å = 10^{-10} m) (effective potential in the united-atom approximation). For comparison: Electrostatic Coulomb potential between two opposite charges of $q = 0.06\ |e|$, where |*e*| is the elementary charge. The energy is given in Kelvin, i.e., divided by k_B, since the thermal energy is in some way the measure of all things in a thermodynamic system.

Since the number of parameters needed to specify the interactions (Eqs. 6 and 7) increases rapidly when several types of molecules must be described (see Example 2. in Section Intermolecular Interactions), empirical rules, called combination rules, are often used to construct the LJ parameters ε and σ for interactions between unlike sites (*ij*) from those for interactions between like sites (*ii* and *jj*). There are several sets of such rules, the most frequently used of which are due to Kong [13] and Lorentz–Berthelot [14]. The Lorentz – Berthelot rule is given here as an example (Eq. 8).

$$\sigma_{ij} = \frac{1}{2} \cdot (\sigma_{ii} + \sigma_{jj}), \quad \varepsilon_{ij} = \sqrt{\varepsilon_{ii} \cdot \varepsilon_{jj}} \tag{8}$$

Another way to simplify the expressions for the intermolecular energies is to attempt to reduce the number of sites used to represent a group of atoms or a molecule. The CH_n-groups in organic molecules are thus often represented by just one site instead of several (e.g., one site on each atom). This is known as the united-atom approximation. It may work if the group is not too polar. Figure 2 shows the interaction potential resulting between two CH_4 molecules, each of which is represented by just one site. We note that this potential is spherically symmetric, and it thus neglects the exact “shape” of the molecule. Typical simulation results for this system are discussed in Examples.

Many other functional forms have been proposed besides the Lennard – Jones ansatz to describe intermolecular interactions of type $U^{(2)}$. The powers 12 and 6 in the LJ-ansatz (Eq. 7) have thus been modified and/or written as functions of *r*. In other instances (e.g., in the Buckingham potential) the inverse power of *r* describing the repulsive part of the potential has been replaced by an exponential function. Alternative forms of molecule–molecule potentials may involve functions of relative molecular orientations instead of sums of site–site potentials. The Gay–Berne model [15], frequently used in simulations of liquid-crystalline systems, again uses a LJ-type form, but with parameters dependent on the relative orientation of two molecules. A detailed discussion of intermolecular interactions in simple systems can be found in, e.g. [16].

3.2.2. *Three-Body and Higher Order Intermolecular Potentials*

Since they are difficult to establish and computationally expensive, three-body ($U^{(3)}$) and higher terms are not often used in simulations. This is an area of active research, and we mention here only two examples among the many approaches.

The three-body Axilrod – Teller interactions [17] (Eq. 9)

$$U^{\text{Axilrod-Teller}} = \frac{\gamma \cdot \left(1 + 3 \cdot \cos\theta_{ij} \cdot \cos\theta_{jk} \cdot \cos\theta_{ki}\right)}{r_{ij} \cdot r_{jk} \cdot r_{ki}} \tag{9}$$

where *i*, *j*, and *k* are three particles, similar to Figure 1, *r* their distances, and θ the angles. This model potential contains only one constant, γ, which can be related to the molecular polarizability [3].

The Sutton – Chen [18] model, which has been used successfully, e.g., in studies of metals and surfaces, is formally similar to an LJ-ansatz with generalized exponents *n* and *m*. The second term, however, is replaced by an average over all interaction partners *j*. This is thus a true many-body potential, and the total potential energy of the *N*-particle system is written as Equation (10)

$$U^{\text{Sutton-Chen}} = \varepsilon \cdot \sum_{i}^{N} \left(\frac{1}{2} \sum_{i \neq j} \left(\frac{a}{r_{ij}} \right)^{n} - b \cdot \sqrt{\sum_{i \neq j} \left(\frac{a}{r_{ij}} \right)^{m}} \right) \tag{10}$$

Five constants, ε, *a*, *b*, *n*, and *m* must be specified here.

An important physical effect neglected in the pair potential approach discussed up to here is the mutual electronic polarization of molecules. There have been many attempts to devise workable schemes allowing to treat the polarization $\vec{P}$ of a molecule efficiently and as exactly as possible in a simulation. $\vec{P}$ can be seen as the additional dipole moment created on a molecule by the electric field $\vec{E}$ generated by its neighbors. In the picture of Figure 1 this would mean that the intermolecular interaction between two molecules, denoted there $U^{(2)}$, is modified by the presence of a third, fourth, fifth molecule in the neighborhood. In the notation of electrodynamics [19], one has $\vec{P} = \overleftrightarrow{\alpha} \cdot \vec{E}$, where $\overleftrightarrow{\alpha}$ is the molecular polarizability tensor. Many difficulties arise: $\overleftrightarrow{\alpha}$ is often not well known; if it is, it is not clear with which site of a molecule it should be identified or how it should be distributed among the possible locations on the molecular frame. Furthermore, if there is more than one polarizable species in the system, an iterative self-consistent procedure is in principle needed to evaluate the energies resulting from this effect: The field generated by the neighborhood polarizes molecule *i*, say, but the changing electric moments (usually only the dipole moment is considered) of molecule *i* will change the electric field experienced by the neighbors, hence their polarization, hence the field acting on *i*, etc., etc. Several sophisticated approximate methods have been proposed to treat this problem (see, e.g., [20], [21]); they cannot be described here. We note, however, that if intramolecular potentials are specified (flexible molecules) some effective mutual polarization will arise from the mutual geometrical distortions of the molecules, e.g., if they lead to distance changes between point charges. In another particularly simple approach, called the fluctuating charge model, the partial electric charges q_i are allowed to vary, e.g., as explicit functions of some distances or angles in the system.

Finally, we note that in certain instances the interaction energies and/or their derivatives, the forces, need not be expressed explicitly as mathematical functions, but can simply be tabulated in one- or multidimensional arrays. Interpolation schemes or splines are then used in the simulations to compute the relevant quantities.

3.3. Example: Intermolecular Potentials for an Aqueous Salt Solution

We stress again that the choice of the interaction model is crucial. It involves the choice of a proper mathematical representation and the choice of all the required parameters. In particular, the choice of the number of sites used to express the intermolecular interactions is crucial. All these choices are largely based on experience and result from a compromise between a representation of the interactions that is as accurate as possible and the resulting computational expenditure required to generate a sufficient number of configurations (see Section Method). An example will illustrate this:

Example 2. A simulation of a solution of a 1:1 salt, say NaCl, in water. The site–site pair potential approach is used for all intermolecular interactions. Rigid molecules (i.e. no intramolecular potentials need to be specified) are assumed and there is no external field.

We consider a system consisting of three species, the solvent (H_2O), cations (Na^+), and anions (Cl^-). The simplest reasonable representation of the water molecules needs three sites (say the atoms O and H), while one site suffices for these simple ions. There are thus four types of sites, leading to (4 × 5)/2 = 10 site–site intermolecular pair potentials $U^{(2)}$ (see Equation 2), which can be arranged in an upper triangular matrix for better visibility:

$U^{(2)\text{O–O}}$	$U^{(2)\text{O–H}}$	$U^{(2)\text{O–cation}}$	$U^{(2)\text{O–anion}}$
	$U^{(2)\text{H–H}}$	$U^{(2)\text{H–cation}}$	$U^{(2)\text{H–anion}}$
		$U^{(2)\text{cation-cation}}$	$U^{(2)\text{cation-anion}}$
			$U^{(2)\text{anion-anion}}$

To write each of these 10 potentials as a sum of a Coulomb interaction (Eq. 6) between electric charges and a Lennard – Jones term (Eq. 7), 20 Lennard – Jones constants (ε and σ, or *A* and *B*) plus four electric partial charges are needed. In this case, it can be assumed that the entire ionic charge of ±|*e*| resides on the ions. The water molecules being neutral, one has $q_O = -2q_H$; there is thus only one parameter to determine, say q_O, which is of the order of magnitude of $q_O \approx -2/3|e|$. As far as the Lennard–Jones parameters are concerned, assuming combination rules (e.g., those in Eq. 8) would reduce the number of parameters to 2 × 4 = 8 for the potentials $U^{(2)}$ in the diagonal of the matrix above, the parameters of

the off-diagonal $U^{(2)}$ resulting from those of the diagonal terms. We note in passing that the notion of "hydrogen bond" does not appear explicitly in the model. The typical features associated with these bonds in terms of structural and dynamical properties of the liquid arise from the interplay between the pair potentials. In any case, it is easily seen that the number of parameters which must be known increases very quickly with increasing complexity of the system, i.e., with the number of species in the system and with the sophistication (or complexity) of the description.

3.4. Data for Interaction Models

Details of the various approaches used to determine consistent sets of parameters for interaction models are beyond the scope of this article. There are essentially three sources of information used for this purpose:

1. Quantum chemistry: This is the "in principle" approach outlined in Chapter Fundamental Approximations. For practical aspects (⟶ Molecular Modeling – Quantum Mechanical Modeling). It will suffice here to say that quantum mechanics, at various levels of approximation (e.g. ab initio, semi-empirical, etc.), can be used to determine, as a function of the relative arrangements of molecules, intermolecular interaction energies in ways very similar to the determination of intramolecular ones. One then endeavors to fit these energies with expressions of type $U^{(2)}$, $U^{(3)}$, etc. We note, in particular, that although the notion of partial charge is not inherent to quantum chemistry, most quantum chemical program packages provide algorithms which help in the determination of these quantities by suitable integrations over the nuclear charges and the wave functions or by fitting procedures.
2. Experiments: Thermodynamic data have frequently been used to gauge the comparative depths of potential wells. Very careful work has, e.g., been carried out to reproduce IR and Raman spectra of many molecules by "harmonic force fields" (essentially the first term in Eq. 3) or higher order expansions. These provide valuable input for intramolecular model potentials. Results from scattering experiments can provide insight into molecular shapes, i.e., essentially the repulsive part of the interaction potential.
3. Simulations themselves: Simulations are often used in a sort of trial and error procedure to refine model potentials, i.e., to adjust potential parameters. Again, this is often done with thermodynamic data. Model potentials have thus been adjusted to yield the proper pressure–density dependence. Self-diffusion coefficients have also been used for such procedures. Some systematic procedures have been proposed recently [22]. Note that there is in general no guarantee that the solution thus found for the interaction model is unique.

In all cases, "true" pair potentials, as constructed, e.g., from quantum mechanical calculations of pairs of molecules, must be distinguished from "effective" potentials, in which averages over the higher order terms are in some way worked into the $U^{(2)}$ term of Eq. 2. Many models, e.g., have a distribution of electric charges (Eq. 6) leading to enhanced dipole moments compared to the gas-phase value in order to account for the average polarization of molecules by their neighbors in a condensed phase. Consequently, such models are in principle valid only for a restricted range of densities and temperatures.

[Top of Page]

4. Approximations for the Simulations

Molecular dynamics simulations are mostly used to study condensed phases, homogeneous or inhomogeneous. They are also very well adapted to studies of interfaces. For the sake of simplicity we shall, however, focus here on simulations of simple homogeneous systems, say a liquid under ambient conditions. The question arises: How many particles does one need for the typical properties of a liquid to be observable? Or, in other words, how many particles/molecules need to be included in the simulation so that the properties determined from this simulation reflect those of a bulk liquid, and not of some sort of cluster, aggregate, or droplet?

Assume for the present qualitative argument the particles to be arranged in a cube with an edge length equal to a multiple of the particle dimension (not worrying what exactly this dimension might be). We consider cubes of 3 × 3 × 3 = 27, 4 × 4 × 4 = 64, 125, 216, 343, . . ., 15 × 15 × 15 = 3375, . . ., particles (the number 3375 being already relatively high for a simulation with anything but the simplest interaction model, although simulations with many more particles have been reported in special cases). Assuming furthermore that the influence of the surface extends about three molecular layers deep into the system, at best (15–6)(15–6)(15–6) = 729 particles would display bulklike properties (i.e., unperturbed by the surface). Thus, in this example, only 729/3375 or 21 % of the particles included in the simulation would contribute to the result. Placing the particles in a sphere would of course improve this ratio, but not decisively.

To avoid this unaffordable inefficiency, the system to be investigated is replaced by a periodic one through the introduction of periodic boundary conditions. The simplest case of cubic periodic boundary conditions is illustrated in Figure 3. The construction is equivalent to replacing the *N*-particle system by a system of *N* cubic primitive lattices: Each particle *i* forms with its image particles *i′* in the neighboring image boxes a cubic primitive lattice. Together with the minimum-distance convention, which stipulates that the interaction is computed between the two closest partners, be they two particles in the basic box or a particle in the basic box and one in a neighboring image box, two advantages are gained:

Figure 3. A system with cubic periodic boundary conditions containing three particles *i*, *j*, and *k* (in red). The basic cube, usually called box, i.e., the volume containing the *N* (here 3) particles of the simulation, is highlighted in red. It is surrounded by 26 (in 2 dimensions 8) "image boxes" (in black), which themselves are surrounded by further boxes. Each image box contains periodic images (in black) of all particles in the basic box. The green box is centered on particle *i*. It can be seen that it contains particle *j* but instead of particle *k* it contains an image *k′*. Under the minimum-distance convention particles *j* and *k′* are the interaction partners of particle *i*. The orange sphere (circle in 2 dimensions) centered on particle *i* indicates that under certain conditions the interactions of particle *i* with particles inside the green box, but outside of this sphere, can be neglected. The radius of the sphere is known as the cutoff radius r_{cut}. If applicable, this procedure can save a lot of computer time, the neglected volume (cube vs sphere) being roughly 50 %.

1. There are no “surfaces” in the system, since each particle is, owing to this construction, at the center of all its interaction partners (green box in Figure 3).
2. The density in the basic box (and thus in the system) remains constant. If a particle leaves the basic box on one side during a simulation, it becomes an image particle. An image particle enters simultaneously on the other side of the box and becomes the particle.

These procedures are not without incidence on some properties computed from an ensemble simulated in this way. In some instances, the correction is easy (maybe even trivial), in others, it is difficult even to estimate its influence. As a rule of thumb, the size of the simulation box and, related through the density of the system, the number of particles, should be chosen in such a way that spatial correlations (expressed, e.g., through the radial pair distribution function; see Chap. Applications) decay over less than half the box length (i.e., from a central particle to the edge). Furthermore, in systems where collective motions (e.g., phonons) play an important role, one should not forget that the box will limit the wavelengths associated with the phenomenon. In mixtures, e.g., solutions, the desired concentration may also set limits as to the minimum number of particles that must be included.

As indicated in Figure 3, the calculations can, under certain circumstances (i.e., when the range of the interactions is short) be accelerated even more by truncating the interactions beyond a cutoff radius r_{cut}, i.e., the potential used in the simulation is given by Equation (11).

$$U^{\text{simulation}} = \begin{cases} U^{\text{model}} & \text{if } r < r_{\text{cut}} \\ 0 & \text{else} \end{cases} \tag{11}$$

There are several ways to implement this truncation scheme [12]. Note that truncation schemes can generate discontinuities in the forces which must be dealt with.

[Top of Page]

5. Constructing the Ensemble

5.1. Method

The task is now to construct a sufficient number of microscopic configurations, or microstates, compatible with the interactions and the macroscopic constraints. We consider only systems set up as described above, i.e., with a fixed number of particles *N* in a fixed (through the periodic boundary conditions) volume *V*. We assume that it is possible to construct one such microstate, i.e., to find positions and velocities for all particles such that the total energy of the system *E* (Eq. 12)

$$E = U^{\text{total}} + E^{\text{kin}} \tag{12}$$

where E^{kin} is the kinetic energy, has a desired value. A series of new microstates, constrained by *N* = const., *V* = const., and *E* = const., can be generated by solving the Newton equation (or any equivalent set of equations) for all particles under the influence of their mutual forces. We shall call this an NVE simulation. Written here, for simplicity, for *N* point masses m_i, i.e., without rotations, these are Equations (13).

$$\begin{aligned} m_1 \ddot{\vec{r}}_1 &= \vec{F}_1\left(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_N\right) \\ m_2 \ddot{\vec{r}}_2 &= \vec{F}_2\left(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_N\right) \\ &\vdots \\ m_N \ddot{\vec{r}}_N &= \vec{F}_N\left(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_N\right) \end{aligned} \tag{13}$$

They are coupled through their right-hand sides, i.e., through the forces. The force acting on mass *i* depends, in general, on the position of mass *i* itself and on the positions of all other masses *j* through Equation 14.

$$\vec{F}_i = -\nabla_i U^{\text{total}} \tag{14}$$

Note that U^{total} (Eq. 2) is given as a function of the site positions, which may or may not coincide with the positions of the masses. In molecules or groups of atoms treated as rigid bodies, the equations become more complex [12], but the principle remains the same.

Additionally to the constraints (NVE), the microstates constructed in this way fulfill the additional constraint of constant total momentum (Eq. 15).

$$\vec{p} = \sum\left(m_i \vec{v}_i\right) = \text{const.} \tag{15}$$

This constant is usually set equal to zero, which facilitates the subsequent evaluation procedures (see Section Simple Averages). The configurations thus generated constitute a particular sample of the microcanonical ensemble of statistical mechanics (see, e.g., [6] or any other book on statistical mechanics) and averages can be computed over this sample, as exemplified in Equation (1).

Except for very few specific cases it is not possible to find a closed, analytical solution of Equations (13). They are thus solved numerically, and several numerical schemes have been devised for this purpose. Without going into details, all these integration schemes can be thought of as procedures in which the following steps are iterated:

1. Knowing the positions and velocities of all particles (sites), calculate all forces (and torques if rigid groups are considered) acting in the system
2. For a short time step δt, allow the particles (a) to move according to their velocities and (b) accelerate according to the forces acting on them
3. Determine new positions and new velocities;
4. Go to step 1

The microstates, or configurations (which we shall denote as $\mathscr{R}$; $\mathscr{R}$ = all positions and velocities of all particles) are thus points on the trajectory of the system evolving with time according to the Newton equation. The generated ensemble can thus be written as a series of configurations ordered according to time and starting at a time origin t_0:

$$\{\mathcal{R}(t_0), \mathcal{R}(t_0+\delta t), \mathcal{R}(t_0+2\delta t), \ldots\ldots\ldots, \mathcal{R}(t_0+M\delta t)\}$$

if *M* integration steps have been carried out. In simulation parlance the term “history” of the system is often used for the trajectory. The availability of the time evolution of the system is the main difference between MD and MC simulations.

The length of the time step δt must be chosen carefully. It should be as large as possible in order to sample the system efficiently (minimize computational costs) but short enough to ensure correct integration of the equations of motion. In NVE simulations, the choice of δt can be checked by making sure that the fluctuations in total energy (which should be zero since *E* = const., Eq. 12) are small compared to real fluctuations in the system, e.g., between kinetic and potential energy. In terms of dynamics, the time-step size must be at least one order of magnitude smaller (say a factor of 20–50) than the period of the fastest motion occurring in the system (e.g., molecular O–H or C–H vibrations, Debye frequency in a solid, etc.). If there are very different motional regimes in the system, it is sometimes possible to use a multiple-time-step method in which the interactions of the slowly fluctuating parts are evaluated less often than those of the fast ones.

We have dealt here explicitly only with the generation of the NVE ensemble. Most simulation packages offer the possibility to generate other ensembles, mostly NVT or NpT, i.e., with constant temperature *T* and/or constant pressure *p* instead of constant energy *E* and/or constant volume *V*. There are various ways to proceed, e.g., by solving additional differential equations associated with “thermostats” and “barostats” or by adding “virtual particles” that act as heat reservoirs; see [23] for details. Both methods may occasionally lead to artefacts [24]. We note in particular that in both cases the dynamics are no longer strictly Newtonian, which may have consequences for the dynamical properties computed from such simulations. However, using these methods for equilibration can facilitate this step, and so an equilibration procedure (see below) using these methods is often combined with a final production run in the NVE ensemble.

5.2. Setting up a Simulation

It was assumed above that a suitable configuration is available to start the simulation. It is by no means obvious how to generate such a configuration but a procedure similar to that outlined in Figure 4 often leads to success.

Figure 4. Schematic equilibration procedure to generate a starting configuration for an equilibrium simulation under NVE conditions.

The particles are placed in the simulation box as “reasonably” as possible, e.g., randomly but with reasonable distances and orientations, or on a lattice or distorted lattice. Velocities are randomly assigned or simply set equal to zero. The integration is started. Assuming the numerical integration works perfectly, the total energy of the system will remain constant. Since the selected configuration will most probably have a surplus of potential energy (a slightly too short interparticle distance on a repulsive part of a Lennard–Jones potential (Eq. 7) suffices) conversion of potential energy to kinetic energy will occur, and the temperature of the system will rise. If the interaction potentials are sufficiently anharmonic, the surplus energy will be redistributed among all degrees of freedom, and the system will converge toward a regime where there are only fluctuations between the two energies, but no systematic drift. (In contrast, a system exhibiting motions of the normal-mode type will not show this behavior.) However, the average kinetic energy (i.e., the system temperature) is now usually much higher than desired. Kinetic energy must thus be removed, either “instantaneously” (as in Figure 4) by scaling the velocities, or more gradually through thermostatting procedures. In any case, since average kinetic and potential energies of a system are interrelated, there will be a relaxation following this adjustment. However, through a series of such adjustments the system can be brought to a state with a total energy compatible with the desired average temperature. All configurations generated during this equilibration procedure are then discarded, except the final one, which is the true initial configuration of the simulation.

It is generally not easy to determine whether one has really reached equilibrium. Necessary conditions are that there should be no drift with time of the kinetic or potential energies, that the particle velocities should follow approximately the Maxwell–Boltzmann distribution, and that the time derivatives of various quantities computed from the ensemble should be zero. However, all this does not guarantee that the system is not trapped in a metastable state.

Equilibration is usually not a problem for homogeneous liquids consisting of small molecules under conditions of temperature and density where the molecular mobilities are not too low (say compared to the time accessible in a simulation, see Figure 5). In mixtures, the equilibration may be more difficult. It becomes a major problem in simulations of systems of large molecules such as polymers or biomolecules.

Another test is to use different starting configurations and equilibration procedures. Once equilibrium has been reached, properties computed over the equilibrium ensemble should of course not depend on the way the equilibrium was reached.

Many simulation programs report observables (such as the system temperature, kinetic energy, potential energy, momenta, etc., and also partial and total averages of these quantities) “on the fly”, i.e., while the simulation is still in progress. While this information is very useful for monitoring the advancement of a simulation and detecting problems, one will eventually want to extract much more information from the simulated ensemble. It is thus necessary to store the configurations on some storage device at time intervals short enough for a subsequent statistical evaluation. This can result in large files. As an example, for a system of 1000 argon atoms, storing just 10 000 configurations (positions and velocities) in single precision (unformatted) would take 1000 (particles) × 10 000 (configurations) × 6 ($x/y/z/v_x/v_y/v_z$) × 4 bytes = 240 Mbyte of storage space.

[Top of Page]

6. Obtaining Results

Once the sample of the thermodynamic ensemble has been constructed, statistical methods can be used to extract the macroscopic observables of the system. This is where a very critical assessment is needed whether the ensemble of simulated configurations is a sufficiently representative sample of the thermodynamic ensemble. Questions to be answered include: Has sufficient decorrelation from the initial configuration been achieved? Could the system be trapped in a metastable state? There are no rigorous methods to tackle these questions, and trial and error methods as well as experience are most often called upon here. Analytical methods [25] can be used in some cases to gauge the reliability of the computed averages in a strictly statistical sense.

Figure 5. Typical space and time domain accessible to molecular dynamics; see text for typical physical phenomena occurring in this domain.

In summary, taking into account the approximations and limitations described above, Figure 5 shows roughly the space–time window accessible to MD computer simulations with today's (ca. 2004) programs and computers. The lower left corner of the graph illustrates the time–space domain of typical fast (in a chemical sense) phenomena such as the electronic transitions observed in optical spectroscopy. The time domain associated with molecular vibrations ranges from femto- to picoseconds; molecular reorientations in liquids have correlation times of several picoseconds. These phenomena can be probed, e.g., by IR and Raman spectroscopy in classical and time-resolved modes, as well as by NMR spectroscopy and dielectric techniques. Longer times are associated with motions of large molecules and with collective motions of groups of smaller ones. The length scale extends from the Ångström range, typical of interatomic distances, accessible experimentally by scattering methods (X-rays, neutrons, etc.), to the nanometer range, which characterizes medium-sized assemblies of molecules. The hydrodynamic regime starts at the top right corner of the graph, it is accessible through other types of simulations (see Chap. Applications).

Two kinds of averages are usually distinguished: Simple averages over all available configurations $\mathscr{R}$, and averages in which the order of the configurations, i.e., the time evolution of the system, is taken into account. In the equilibrium ensemble, this is most often done by computing so-called time-correlation functions. We note here, without going into detail, that these time-correlation functions and the spatial correlations briefly discussed below can be seen as limiting cases of a general space–time function [6].

6.1. Simple Averages

The average value of a quantity A, denoted $\langle A \rangle$, is computed as Equation (16)

$$\langle A \rangle = \frac{1}{M} \cdot \sum_{i}^{M} A(\mathcal{R}_i) \tag{16}$$

where A is a quantity that can be determined from the particle positions, velocities, (and possibly forces) contained in the system configurations R_i. Equation (1) is an example of this procedure. Another example follows from the equipartition theorem of statistical mechanics, written in Equation (17) for a system of N masses

$$\frac{3N-3}{2} \cdot k_B \cdot \langle T \rangle = \langle E^{kin} \rangle = \frac{1}{2} \cdot \sum_{i}^{N} m_i v_i^2 \tag{17}$$

where k_B is the Boltzmann constant, $\langle E^{kin} \rangle$ is the average kinetic energy and $\langle T \rangle$ the average temperature. The term $3N$–3 is the number of degrees of freedom in this system. The three degrees of freedom corresponding to the movement of the center of mass must be removed by virtue of Equation (15). In general, for systems with constraints or with molecules represented by rigid or semirigid entities, the real total number of degrees of freedom must be entered into Equation (17) instead of $3N$–3. Examples of such averages are, besides $\langle T \rangle$ in Equation (17), the average potential energy $\langle U \rangle$, the average pressure $\langle p \rangle$, and many other thermodynamic quantities which can be directly related to experimental values. Thermodynamic quantities involving derivatives can be obtained from fluctuations (e.g., heat capacities, for which quantum corrections may have to be included) or by more advanced statistical mechanical treatments [26-28]. Spatial correlations like the radial pair distribution function (RDF) $g(r)$ or its analogue, the radial pair correlation function $h(r) = g(r)$–1, are routinely computed. These functions are suitably normalized histograms over interparticle distances between pairs of molecules; they are related to the so-called potential of mean forces (PMF) and are often used in thermodynamics calculations [6]. They are furthermore related through Fourier transformations to the scattering functions obtained in X-ray

or neutron scattering experiments [29].

We note that in Equation (16) the result will not depend on the order of the configurations $\mathcal{R}_i$. The fact that the $\mathcal{R}_i$ were constructed using the Newton equation is thus of no consequence. Quantities like $\langle A \rangle$ are thus often termed "static" or "structural". If they depend only on the positions they can also be obtained from Monte-Carlo (MC) simulations, in which the ensemble is constructed through a random-walk procedure.

6.2. Time-Correlation Functions

The time-correlation function $c_{BC}(t)$ between two quantities B and C is defined in the equilibrium ensemble as Equation (18)

$$c_{BC}(t) = \langle B(\mathcal{R}(\tau)) \otimes C(\mathcal{R}(t+\tau)) \rangle_\tau \tag{18}$$

where $B(\mathcal{R})$ and $C(\mathcal{R})$ are quantities like $A(\mathcal{R})$ above, $\otimes$ denotes a general operator (most often a product or scalar product, sometimes also a logical AND or OR operator) and $\langle\ \rangle_\tau$ denotes an average over all times τ. If $C = B$, $c_{BB}(t)$ is called an autocorrelation function. Otherwise, it is called a cross-correlation function.

Example 3. One of the simplest and most widely studied autocorrelation functions is the velocity autocorrelation function, i.e., $B(\mathcal{R}) = \vec{V}$, where $\vec{V}$ is the vector of the velocities of N equivalent particles (e.g., the same type of atom, or a given type of atom fulfilling some condition) at a given time (Eq. 19).

$$\vec{V}(\mathcal{R}(t)) = \begin{pmatrix} \vec{v}_1 \\ \vec{v}_2 \\ \vdots \\ \vec{v}_N \end{pmatrix} \tag{19}$$

The velocity autocorrelation function then becomes in terms of the $\vec{v}_i$ Equation (20)

$$\begin{aligned} c_{\vec{V}\vec{V}}(t) &= \left\langle \vec{V}(\mathcal{R}(\tau)) \cdot \vec{V}(\mathcal{R}(t+\tau)) \right\rangle_\tau \\ &= \frac{1}{N \cdot M} \sum_{j=0}^{M} \sum_{i=1}^{N} \left(\vec{v}_i(\tau_j) \cdot \vec{v}_i(\tau_j + t) \right) \\ &= \left\langle c_{\vec{v}_i \vec{v}_i}(t) \right\rangle \end{aligned} \tag{20}$$

Equation (20) can be easily evaluated from the trajectory; an example is given in Sect. Examples

Integrals of correlation functions of the type Equation (21)

$$\mathrm{T} = \lim_{t \to \infty} \int_0^t c_{AA}(\tau) \mathrm{d}\tau \tag{21}$$

are related to transport properties, in the case of the velocity autocorrelation function, to the self-diffusion coefficient D_S. For the integral to converge, the correlation function must decay within the simulation time. Actually, it must decay much faster so that a sufficient number of averages (the sum over j in Eq. 20) can be carried out. If the expectation value of the autocorrelated quantity is not equal to zero, the definition of the function is usually modified so that it indeed decays to zero at long times.

Classical time correlations are even in time. It is thus sufficient to consider their Fourier–Laplace transforms. For a function $c_{AA}(\tau)$, the transform (Eq. 22)

$$\tilde{c}_{AA}(\omega) \propto \int_0^\infty c_{AA}(\tau) \cos(\omega\tau) \mathrm{d}\tau \tag{22}$$

is called the spectral density, or the simply the spectrum. Depending on which quantity A is correlated, the spectra can be observed experimentally (e.g. in IR spectroscopy, corresponding to the correlation of the dipole moment or derivative of the dipole moment of the system). The velocity autocorrelation function is again used as an example in Chapter Examples.

[Top of Page]

7. Examples

The first example is a simulation of a system consisting of 864 Lennard–Jones particles (Eq. 7) parameterized to represent methane (CH_4, united-atom approximation, effective potential from Figure 2) in an NVE simulation with volume and energy chosen to yield an average temperature (Eq. 17) of $\langle T \rangle$ = 130 K and a density of 0.3952 g/cm^3. Figure 6 shows the simulated radial pair distribution function (RDF) $g(r)$, which is a measure of the microscopic structure in a liquid [29]. It represents the relative density, compared to the overall bulk density, as a function of distance from a fixed particle at $r = 0$. In the region of the first peak, located roughly where the Lennard–Jones potential has its minimum, the local density is thus enhanced by a factor of approximately 2.6. These density fluctuations extend to further "shells" of neighbors, and finally the $g(r)$ function converges toward a value of 1 (bulk density). RDFs can be determined experimentally, under certain approximations, from X-ray, neutron, or other scattering methods; they are also an important tool for the computation of thermodynamics quantities in statistical mechanics.

Figure 6. Radial distribution function $g(r)$ of liquid methane at $\langle T \rangle$ = 130 K and a density of 0.3952 g/cm^3.

Figure 7. Normalized VACF of liquid methane and integral of the unnormalized function, yielding at long times a self-diffusion coefficient of $D_S \approx 6.66 \times 10^{-9}$ m^2/s.

As outlined in Section Time-Correlation Functions, dynamical quantities are accessible by computing suitable time-correlation functions. The self-diffusion coefficient D_S of liquid methane is thus obtained from the molecular velocity autocorrelation function (VACF) using Equations (20) and (21). The underlying simulation was run under the condition of zero total momentum $\vec{p}$ = 0 (Eq. 15), i.e., the expectation value of a particle velocity is zero (see above). Figure 7, left axis, shows this VACF, normalized to unity at t = 0. The right-hand scale in Figure 7 refers to an integral like in Equation (21), suitably normalized to yield at long times the self-diffusion coefficient D_S.

To illustrate the real movements of some methane molecules during a simulation, Figure 8 displays the projections onto a plane of four particle trajectories generated during 25 ps of simulation time. We note that this time is much longer than the correlation time of the velocities in Figure 7. Such plots are useful to gauge how extensively the thermodynamic ensemble has been sampled by the simulation.

Figure 8. Trajectories of four different arbitrarily chosen methane molecules over 25 ps of simulation. The frame represents the quadratic simulation box with a side length of 38.8 Å. Initial and end points are marked by a bold circle.

8. Applications

The applications of MD simulations are by now almost innumerable, and only a few examples can be given here. The first examples, discussed in the previous sections, were taken from studies of liquids such as liquid methane or aqueous ionic solutions at ambient conditions, for which much of the basic methodology was developed. However, one of the main advantages of simulation methods is that no assumptions have to be made concerning the state of the system: gases, liquids, and solids, as well as inhomogeneous systems containing all kinds of interfaces, are thus, in principle, amenable to MD simulations. As a caveat, we note, however, that in some cases this method will be quite inefficient. In gases at low densities, for instance, very much time is spent integrating the motions of molecules with almost negligible mutual interactions.

It is easy in MD simulations to study systems under extreme conditions of density (pressure) and temperature; such systems are usually difficult to study experimentally. Thus, molten salts were among the first systems studied by simulation techniques. Studies of liquids of geological interest, i.e., usually at pressures and temperatures difficult to maintain in a laboratory experiment, are other examples for this kind of approach. Supercritical fluids in thermodynamic conditions not too close to the critical point can be investigated in the same fashion. Studies on highly complex liquids such as polymer melts or liquid crystalline systems are becoming more and more numerous as the available computational resources increase and models and methods for their simulations are developed.

Besides neat liquids and solutions, the structure and dynamics of liquid mixtures has become a very active field of investigation. We note here, however, that studies of certain thermodynamic properties, in particular of the phase equilibria, are most often undertaken by using specific Monte-Carlo (MC) techniques rather than MD simulations. The development of adequate interaction models, i.e., ones able to represent both the neat liquids and the mixtures, is one of the main challenges when mixtures are to be studied.

Among the many applications concerning interfaces (liquid–liquid, liquid–gas, and solid–liquid) the free surfaces of pure liquids and solutions have been studied. Furthermore, liquids near smooth hydrophilic or hydrophobic walls with or without corrugation have been extensively simulated. Systems of electrochemical interest, e.g., solid metal electrodes in contact with aqueous ionic solutions, but also confined liquids such as liquids in pores or in clays, have been of particular interest. The dissolution and crystallization processes of salts have been investigated in simulations of salt solutions in contact with the corresponding crystals. Layers of amphiphilic molecules, soap films, micelles, and micellar solutions of various kinds

have been investigated in very extensive MD simulations, as have polymer layers and model biomembranes. In some of the studies on interfacial or porous systems it is sufficient to consider the solid phase as an immobile “frozen” obstacle. However, if the dynamics of such crystalline solids are to be simulated, which is often necessary, the restrictions imposed by the periodic boundary conditions must be considered. Multiples of the elementary cell are used as simulation boxes, and special techniques are available to adjust the box, e.g., if structural phase transitions are to be studied. Multiple studies on inclusion compounds such as clathrate hydrates and zeolites, with or without guest molecules, have been carried out in this way.

The biosciences are by now possibly the largest application domain for MD simulations. The main problems here are the sizes of the systems and the consequent complexity of the interaction models. Furthermore, in many instances these systems are characterized by correlation times that are long compared to the times usually accessible in MD simulations (see Figure 5). Extremely long simulation runs are thus necessary, and present-day resources often do not allow a satisfactory sampling. Yet events like the penetration of small solvated molecules, or indeed water itself, into membranes or trans-membrane ion channels have been studied by simulation techniques. Derived techniques are used in drug design. Understanding protein folding remains one of the challenges in this area, and large-scale efforts are underway. This is, however, beyond the scope of this article.

As discussed above, transport coefficients can be obtained, within the framework of the fluctuation-dissipation theorem [6], from correlation functions computed for the system in equilibrium (see Section Time-Correlation Functions). However, it is often more efficient to perform nonequilibrium molecular dynamics (NEMD). This can be done both for stationary (e.g., in a thermal gradient) and nonstationary (e.g. for relaxation phenomena) conditions. Many methods have been proposed [12], [30-32]. Essentially, in the first instance, gradients are maintained across the system during the simulation in a way compatible with the periodic boundary conditions. In the second instance, an equilibrium simulation is performed and configurations are periodically extracted, perturbed, and their evolution is compared with the ongoing equilibrium run. The NEMD simulation allows one to go beyond the linear response and to study nonlinear transport phenomena.

In a coarse-graining approach, macroscopic quantities obtained from MD simulations are often used as input parameters to other types of simulations, e.g. Brownian Dynamics [12] or dissipative particle dynamics (DPD) [33]. In these approximations, much larger systems can be studied over longer periods of time, going well beyond the domain sketched in Figure 5.

Finally, we note that more and more approaches combining MD simulations (in thermodynamic equilibrium, as discussed here, or out of equilibrium) with other approaches are being proposed for various purposes. Chemical reactions are thus tackled by combining MD with quantum chemistry calculations. Other efforts aim at extending the space and time domains accessible to the simulations by using suitable coarse-graining techniques. These methods are mostly still in the stage of methodic developments. Like the now classical methods discussed here, which were developed in the last third of the 20th century, they will one day become tools for research in all kinds of disciplines.

Symbols and Abbreviations

***A*, *B*, *C*:** state functions, i.e., functions that can be computed knowing a configuration

A_{ij}, B_{ij}**:** parameters of the Lennard–Jones (12–6) potential

$\overleftrightarrow{\alpha}$**:** molecular polarizability tensor

$c_{BC}(t)$**:** time correlation function between state functions B and C

***d*:** interparticle distance

***D*:** depth of Morse potential

D_s**:** self-diffusion coefficient

δt**:** time step size

|*e*|: elementary electric charge

$\vec{E}$**:** electric field

***E*:** total energy of the system

E^{kin}**:** kinetic energy

ε**:** parameter of the Lennard–Jones (12–6) potential and of potentials derived from the LJ potential

$\vec{F}_i$**:** force acting on particle *i*

Υ**:** constant of the Axilrod–Teller potential

***h*:** Planck's constant, $h = 6.62608 \times 10^{-34}$ J s

$\vec{k}$**:** wave vector

k_B**:** Boltzmann's constant, $k_B = 1.38066\ 10^{-23}$ J/K

k_{lm}, k_{lmn}, k_{lmno}**:** (generalized) force constants

Λ**:** De Broglie wavelength

m_i**:** mass of particle *i*

***M*:** number of events or occurrences

M_{dof}**:** degrees of freedom

***N*:** total number of particles in a simulated system

ω**:** angular frequency

***p*:** pressure

$\vec{p}$**:** momentum

$\vec{P}$**:** molecular polarization

q: electric (partial) charge, i.e. multiples of the elementary charge |*e*|

$\mathscr{R}$: configuration

$\vec{r}_i$: vector x_i, y_i, z_i of particle coordinates

$\ddot{\vec{r}}_i$: acceleration of particle *i*

$\vec{r}_{ij}$: position of site *i* relative to *j*, $(\vec{r}_i - \vec{r}_j)$

r_{cut}: cut-off radius

ρ: internal coordinate

S: length of the periodic box

σ: parameter of the Lennard–Jones (12–6) potential

t, τ: time

T: absolute temperature

T: transport property

θ: angle

U: potential energy

V: volume

$\vec{V}$: vector of velocities

$\vec{v}_i$: vector V_{x_i}, V_{y_i}, V_{z_i} of particle velocities, $\vec{v}_i = \dot{\vec{r}}_i$

$\langle\ \rangle$: average over configurations

CPMD: Car–Parrinello molecular dynamics

DFT: density functional theory

DPD: dissipative particle dynamics

LJ: Lennard–Jones

MD: molecular dynamics

MC: Monte Carlo

NpT: isothermal–isobaric ensemble

NVE: microcanonical ensemble

NVT: canonical ensemble

NEMD: nonequilibrium molecular dynamics

RDF: radial distribution function *g*(*r*)

VACF: velocity autocorrelation function

1. Introduction

Many effluents emitted from chemical, petrochemical, and pharmaceutical production plants contain volatile organic compounds (VOCs). Furthermore, hydrocarbon vapors are generated by handling, storage, and distribution of solvents and gasoline. Hydrocarbon vapors are known as ozone precursors and are one facsstor causing the formation of summer smog. In addition, hydrocarbon vapors are believed to be greenhouse gases. Aromatic hydrocarbons such as benzene are considered to be carcinogenic. The introduction of new clean air acts with new and more stringent emission standards has generated a driving force to develop new and more efficient off-gas treatment units. Membrane-based separation technologies for the recovery of organic vapors from gaseous effluents were introduced on a commercial scale in the early 1990s [1]. Since ca. 1995 the acceptance of this technology has been growing because of its confirmed performance, reliability, and economic operation. Based on the experience gained with end-of-pipe applications, the use of membranes in integrated processes to separate organic compounds has been explored. Well-accepted applications are the use of membranes in polymer production processes for separation of olefins (ethylene, propylene) from process streams, separation of hexane and vinyl chloride monomer, and nitrogen purification. Newly explored applications are hydrocarbon dewpointing of natural gas, treatment of associated gas from oil production, and control of methane number of the feed gas for combustion engines.

2. Membranes

Membranes which are commonly used in organic vapor separation applications are flat-sheet thin-film composite membranes. Typically, the membrane consists of a multilayer structure. Nonwoven materials, e.g., polyester or polypropylene fleeces, are used as substructure to provide the necessary mechanical strength. A microporous substrate made from polysulfone, polyimide, polyacrylonitrile, or poly(vinylidene fluoride) is cast on the fleece [2]. Pore size and pore distribution of the substructure must be formed in accordance with the viscosity and adherence of the coating solution which is applied on top of the microporous substrate to form the dense selective film. Common membrane polymers to separate organic vapors from permanent gases are polydimethylsiloxane (PDMS) and polyoctylmethylsiloxane (POMS) [3]. Dense

10.1002/14356007.j16_j01

thin films with a thickness of 1 – 5 µm have adequate selectivity and sufficient permeance for a variety of organic vapors. Compared to PDMS, POMS has higher selectivity but lower permeability. The advantage of the higher selectivity is the reduced copermeation of compounds to be retained on the feed side of the membrane. This results in reduced sizes of feed and permeate pumps but also in increased membrane area. Investment and operating costs must be considered when selecting the membrane polymer. The flat-sheet membranes are employed in spiral-wound or envelope-type modules for technical configurations.

3. Membrane Selectivity

Gas transport through a dense film depends on the interactions of the feed-gas compounds with the membrane polymer regarding its solubility and diffusivity. The diffusion coefficient of a gas molecule is expected to decrease with increasing molecular size. This is true in the case of glassy polymers with stiff polymer backbones, which act like molecular sieves. Small molecules like helium, hydrogen, or nitrogen permeate much faster through the rigid polymer backbone than larger molecules such as butane or pentane. An elastomeric polymer behaves more like a liquid. Gas transport through rubbery polymers is more determined by its solubility than its diffusivity. The diffusion and solubility coefficients of different gases in silicone rubber are depicted in Figure 1 [4].

Figure 1. Diffusion and solubility coefficients of different gases in silicone rubber at 30°C [5 – 7] versus the critical volume

It is apparent that the slower diffusion of hydrocarbons like propane, butane, and pentane is overcompensated by their higher solubility. As a result silicone rubber is more permeable for hydrocarbons than for permanent gases like oxygen or nitrogen. The plot in Figure 2 shows the selectivity of various hydrocarbon vapors over nitrogen. The organic compounds are arranged with respect to their material category.

Figure 2. Selectivities of various organic vapors versus nitrogen

The length of the bars shows the highest selectivity determined by single-gas measurements at ambient temperature. The selectivities obtained in real technical membrane separation processes are lower and depend on process

and design parameters like pressure, temperature, feed-gas composition, gas velocity over the membrane on the feed side, pressure drop in the membrane module, and module and membrane design. Especially the impact of concentration polarization caused by the formation of a boundary layer adjacent to the membrane surface has a strong impact on the overall selectivity of the separation process.

3.1. Temperature, Pressure, and Feed-Gas Concentration

The process operating temperature has a direct influence on the membrane selectivity. The diffusion coefficient of gas molecules increases with increasing temperature. However, the permeance of organic vapors through elastomeric polymers is governed by their solubility, which increases with decreasing temperature. Hence, the permeation of organic compounds increases with decreasing temperatures, whereas the permeation of diffusion-driven compounds like nitrogen or oxygen decreases (Fig. 3). It is advantageous to perform separation of organic vapor at the lowest possible operating temperature in order to achieve the highest possible membrane selectivity.

Figure 3. Temperature dependence of gas and vapor permeation through PDMS membranes

Silicone-based membrane materials swell in the presence of organic compounds depending on their vapor pressure. The presence of permanent gases like oxygen, nitrogen, or hydrogen has no impact on membrane swelling. The sorption of organic compounds plasticizes the membrane material and increases the diffusion coefficient. Membrane swelling leads to a higher permeance of all gas and vapor compounds (Fig. 4).

Figure 4. Flux densities of organic vapors and nitrogen over vapor pressure (single-gas measurements)

3.2. Real-Gas Behavior

The membrane permeance is defined by

$$L_i = \frac{\dot{V}_{i\,\mathrm{P(STP)}}}{A_\mathrm{M} \cdot (p_{i\mathrm{H}} - p_{i\mathrm{L}})} \tag{1}$$

where L_i is the permeance, $\dot{V}_{i\,\mathrm{P(STP)}}$ is the permeate volume rate in the standard state, A_M is the membrane area, and $p_{i\mathrm{H}}$ and $p_{i\mathrm{L}}$ are the partial pressures of components at the feed and permeate side of the membrane, respectively. The partial pressures must be replaced by fugacities in medium- and high-pressure applications in order to avoid a faulty process design.

At pressures exceeding 10 bar the driving force of higher hydrocarbons is reduced by the real-gas behavior. The difference in partial pressures must be replaced by the difference in fugacities. A comparison of the partial pressure difference and fugacity difference driving forces versus total feed pressure is plotted in Figure

5 for a binary mixture with 5 % n-butane in methane.

Figure 5. Calculated ideal and real driving force of n-butane in a binary mixture of n-butane and methane [8]

The dependence of fugacities of some organic vapors on pressure is depicted in Figure 6. Clearly, real-gas behavior cannot be neglected at operating pressure exceeding 10 bar.

Figure 6. Influence of pressure on real gas behavior of organic vapor compounds [9]

3.3. Concentration Polarization

The design and selection of membrane and membrane module is highly dependent on process and operating conditions. The thickness of the selective layer of the composite membrane should be in accordance with permeance and selectivity of feed compounds, as well as the Reynolds number of the feed volume flow over the membrane surface. The feed flow Reynolds number has a direct influence on the thickness of the boundary layer between the bulk gas and the membrane surface. The thickness of the selective layer has a reciprocal dependency on the gas and vapor permeance. The porous substructure of the membrane must be as open as possible to provide a nearly unrestrained flux of all permeating compounds. Boundary layer, selective layer, and porous support create the major transport resistances (Fig. 7). The behavior of the selective layer and the buildup of the boundary layer are interdependent. A high permeance of a fast compound will increase the influence of the boundary layer, resulting in high concentrations of the slow compounds and low concentrations of the fast compounds on the membrane surface. This effect decreases the driving force for the preferentially permeating component (cf. Eq. 1). Transport through the boundary is of diffusive nature. Hence, concentration polarization is of increasing importance with increasing operating pressure, since the diffusion coefficient is inversely proportional to pressure.

Figure 7. Gas transport through polymer membranes

3.4. Joule – Thomson Effect

The Joule – Thomson effect must be taken in account if the transmembrane pressure difference is high [10]. The temperature change in a membrane module is caused by two effects:

- Adiabatic throttling of the permeating gas

- Heat transfer from the high- to the low-pressure side of the membrane

The Joule – Thomson effect is of major importance for high-stage-cut separation. The stage cut is defined as permeate volume flow over feed volume flow. In this case it is insufficient to design a gas separation process solely in terms of material balances, permeation equations, and mass transfer kinetics. The energy balances must also be taken in account. The temperature change along the membrane module has a direct influence on permeances and selectivities, since they are functions of temperature. In case of natural gas applications a heat-recovery system in front of the separation stage could improve the overall process efficiency [11].

4. Applications

4.1. Gasoline Vapor Recovery

Fuel distribution is considered to be an area with a major potential for reduction of VOC emissions. The principle of emission reduction in the chain of gasoline distribution from refinery to tank farm, gas station, and car refueling is vapor balancing. The volume of vapor which is displaced when a volume of liquid is filled into a tank is collected and returned to the tank from which the liquid is drawn off. The gas volume is increased because of possible changes of temperatures and pressures as well as by evaporation of low-boiling substances, which are generated by turbulences of the liquid phase during filling procedures. If the principle of vapor collection is consistently applied throughout the complete chain of gasoline distribution, nearly all generated vapors can be separated and recovered in a central vapor recovery unit (VRU) at a refinery or tank farm. The average gasoline vapor concentration in off-gases from tank farms is approximately 20 – 40 vol %, which corresponds to approximately 600 – 1200 g hydrocarbons/m^3 air. This amount also represents a commercial value which should be recovered, especially if the distributed gasoline was taxed. The stringent air-quality control requirements are laid down in clean air acts, ordinances on the reduction of hydrocarbon emissions, or technical instructions on air quality control [12 – 14]. Most of the provisions are considerably more stringent than the European Directive 94/63/EC, which allows an emission limit value for hydrocarbons of 35 g/m^3. This is far from reflecting best available technology (BAT) of vapor recovery units. It is also dangerously close to the lower explosion limit (40 g/m^3) of gasoline vapors and thus represents a safety risk.

Gasoline vapors are generated by tank filling, storage-tank ventilation, and operation of truck filling stations, rail wagon filling stations, or ship loading facilities. If a constant off-gas flow is expected, the off-gas can be directly fed to the vapor recovery unit. In case of fluctuating off-gas volumes it can be recommended to install a gas holding tank to collect vapors between the emission source and the vapor recovery unit in order to smooth out volume peaks. Buffering of off-gas volumes leads to a plant design according to an average off-gas flow and a continuous plant operation (Fig. 8).

Figure 8. Flow sheet for gasoline vapor recovery technology

Figure 9. Flow scheme of a hybrid vapor recovery unit consisting of a membrane stage and pressure swing adsorption unit

The first processing step is pressure increase. Typically, liquid-ring compressors or screw compressors are used. The gasoline is recovered by condensation or absorption before the off-gases are fed to a membrane stage. The membrane stage is designed according to the required vent-gas purity. The membrane separates hydrocarbon vapors from air. Hydrocarbon permeates through the membrane, whereas the air remains on the feed side of the membrane. A pressure ratio (feed pressure over permeate pressure) of 6 – 10 must be applied to support the membrane separation process. Liquid-ring compressors operate at 3 – 3.5 bar, whereas the screw compressors operate at a feed pressure of approximately 6 – 9 bar.

In liquid-ring compressor applications, the membrane separation process is supported by applying vacuum at the permeate side. The permeate stream, enriched in hydrocarbon vapor, is recycled to the intake of the feed compressor. Single-stage membrane units are very efficient up to a residual vent-gas concentration of 4–35 g/m^3 of organic compounds. If stringent clean air acts require lower outlet concentrations post-treatment by pressure swing adsorption or combustion can be recommended. A hybrid system consisting of a membrane stage and a polishing step by pressure swing adsorption (Fig. 9) is the best-selling system combination.

This combination has some essential advantages. The operating pressure of the membrane process can be used advantageously to support the adsorption stage, whereas the vacuum can be used to support the desorption of the regenerating adsorber column. Because of the low and defined retentate concentration the temperature increase caused by adsorption is less than 5°C. The system is also characterized by the ease of shutdown and startup (Fig. 10).

4.2. Retrofitting of Activated Carbon Based Vapor Recovery Units

Existing activated carbon based vapor recovery units erected in the early 1980s often do not meet current clean air standards, which are adapted to developments in separation techniques. A possibility to improve the overall performance of an adsorption unit is the installation of a membrane stage to precondition the feed stream to the adsorption unit. By means of the membrane stage higher hydrocarbons and peak concentrations are separated and a stream nearly constant in hydrocarbon concentration is fed to the adsorption plant. The history of the improvement of an adsorption unit is shown in Table 1.

Table 1. Steps to improve the performance of an existing adsorption unit

	Initial conditions	1st retrofitting (enhancement of vacuum pump capacity)	2nd retrofitting (installation of membrane stage)	3rd retrofitting (enhancement of blower capacity)
Emissions	> 3 kg/h	3 kg/h	< 150 mg/m^3 goal, 20 mg/m^3 actual	< 150 mg/m^3 goal, 70 mg/m^3 actual
Electric power (installed)	64.5 kW	94.5 kW	131.5 kW	131 kW
Electric power (consumed)	57 kW	86 kW	118 kW	120 kW
VRU capacity	280 m^3/h	280 m^3/h	280 m^3/h	350 m^3/h
Specific power requirement	0.2 kW/m^3	0.31 kW/m^3	0.42 kW/m^3	0.34 kW/m^3

Figure 10. Gasoline vapor recovery unit. Interior view of a container unit (used with permission of Borsig Membrane Gas Processing)

The first step of plant improvement was the enhancement of vacuum pump size to make desorption more efficient and to improve the adsorption capacity. This measure led to emissions of 3 kg/h. To meet the stipulated goal of < 150 mg/m^3, a vacuum-assisted membrane stage was installed (Fig. 11). Higher hydrocarbons are separated efficiently by membranes, and the separated permeate stream is fed to the existing absorption unit for recovery. The stream with a residual content of organic vapor is finally treated by the adsorption unit. At the same feed volume flow the emission was reduced to 20 mg/m^3. This low emission allowed an increase of feed volume flow. Because of spare capacity of the blower at the outlet of the adsorption unit the feed volume flow could be increased from 280 to 350 m^3/h. The outlet concentration was still half of the allowed limit, and the specific power consumption of the plant could be reduced from 0.42 to 0.34 kW/m^3.

Figure 11. Retrofitting of an adsorption unit by installation of a membrane stage

4.3. Emission Reduction at Gas Stations

The end of the chain of gasoline distribution is the gas station. Emissions are generated by car refueling and from the stack of the storage tanks. The refueling emissions are reduced by returning the vapors by means of vacuum-assisted systems or balance systems. Vapors generated by car refueling at the filler neck of the car tank are collected by a device at the nozzle of the gasoline dispenser. Stack emissions are caused by a higher vapor return rate, evaporation of unsat-

urated air, temperature change, changes in ambient temperature, and refilling of the storage tanks. To avoid emission transfer from the car tank neck to the storage tank stack an air to liquid ratio of 1:1 has been stipulated. The capture of the refueling emissions is highly dependent on the design of the car tank neck. Investigations by TÜV Rheinland have shown that the capture efficiency is limited to an average of 75 % [15]. Meanwhile, neck designs with optimized and improved capture rates have been demonstrated. Tests have shown that an increase of the vapor return ratio from 1:1 to 1.5:1 leads to a higher vapor capture efficiency of 95 – 99 % [16]. Enhanced vapor return rates are only allowed if a vapor recovery unit with efficiency higher than 97 % is installed in order to separate and recover the gasoline vapors [14].

An essential requirement is leakage-proof installation of tanks, pipes, and dispensers. The storage tank stocks must be equipped with pressure/vacuum valves and the tank-filling pipes and vapor balancing pipes with check valves to avoid uncontrolled emissions. The system for the control of stock emissions (Fig. 12) consists of a membrane module (6), vacuum pump (7), pressure gauge (9), and a pneumatic control valve (10). The pressure gauge measures the pressure difference between tank head space and atmospheric pressure. If the pressure difference reaches a given set point, the vacuum pump (7) is started, the control valve opens by means of the applied vacuum at the permeate side, and the tank pressure is released by passing the head space vapors over the membranes arranged in the membrane modules. The gasoline vapors are separated from the vent stream and returned to the head space of the storage tank.

4.4. Off-Gas Treatment in the Chemical Industry

Dichloromethane (DCM) is a solvent which is commonly used in chemical production. DCM is considered to be a hazardous compound. The allowed effluent concentration is 20 mg/m^3. Figure 13 shows a flow scheme of a DCM separation plant for the treatment of highly concentrated off-gas streams. The operating conditions and relevant information on process data are listed in Table 2.

Figure 12. Vapor recovery at gas stations

Figure 13. Flow scheme of a DCM recovery plant

Membrane separation can be advantageously applied to treat concentrated gas and vapor streams. The membrane is often used as prestage to optimize recovery by adsorption or condensation. Figure 14 shows a combination of adsorption and membrane technology to treat low-concentration off-gas streams. The off-gas from a production plant is contaminated with low concentrations of DCM and ethanol (EtOH) and is saturated with water vapor.

The off-gas is cooled to reduce the water content before a booster feeds the stream to the adsorption stage. Two parallel arranged adsorber units are installed to treat the off-gas. One unit is in the adsorbing phase, whilst the other unit is in the regeneration phase. The cycle time is approximately 10 min. Regeneration is facilitated by applying a vacuum of 100 mbar and purging the column with a fraction of cleaned air from the unit in adsorption operation. The DCM- and EtOH-enriched desorption stream is compressed to 6 bar and the organic vapors are liquefied at 15°C. Residual organic vapors are separated by the membrane stage after the condensation step and recycled to the liquid ring compressor for recovery. The gas leaving the membrane stage is fed to the adsorption stage in operation for final purification. Technical data for the process follow:

Off-gas intake	$450\,m^3{}_{STP}/h$
DCM concentration	max. $20\,g/m^3{}_{STP}$
EtOH	max. 10
Purge	$75\,m^3{}_{STP}/h$
Desorption pressure	< 100 mbar abs
Feed pressure	6 bar abs
Condensation temperature	15°C
Cycle time	ca. 10 min
Concentration purge to recovery	$< 1\,g_{VOC}/m^3{}_{STP}$
Residual DCM concentration	$< 20\,mg/m^3{}_{STP}$
Residual EtOH concentration	$< 150\,mg/m^3{}_{STP}$

Figure 14. Hybrid system: First stage adsorption, second stage strip gas treatment by membrane separation (by permission of Satorius AG)

4.5. Recovery of Vinyl Chloride Monomer from Off-Gas of PVC Production

Vinyl chloride monomer (VCM) in off-gas from PVC production must be recovered because of its high commercial value. Residual concentrations from the recovery stage must be separated in view of its impact on the environment and

human health. The conventional vinyl chloride recovery process is depicted in Figure 15.

Figure 15. Conventional vinyl chloride recovery process

Figure 16. VCM recovery rate and residual concentration versus condensation temperature

The commonly used recovery process is compression of the off-gas to 5.5 bar and condensation in multistage condensers. The first condenser is operated with cooling tower water at ambient temperature, the second condensation is performed at –10 to –15°C and the third stage at approximately −40°C (92 % recovery). The residual VCM concentration leaving the recovery stage is 0.18 kg/m$^3_{\mathrm{STP}}$ (Fig. 16).

Besides the considerable residual concentrations another disadvantage is ice formation on the condenser surface when water vapor is present in the off-gas. Two parallel pressure condensation stages must be installed to perform a continuous recovery operation. The second and third condensation stages can be replaced by a membrane stage. Depending on the membrane stage layout separation efficiencies can be achieved which are comparable with those at condensation temperatures of −70°C. Figure 17 shows retrofitting of a multistage condensation unit.

Figure 17. Retrofit of a multistage condensation unit. The separated VCM vapors are recycled to the gas holder and recovered in the first condenser operated with cooling water at ambient temperature

4.6. Batch Reactions and Vacuum Drying of Fine Chemicals

The drying process starts at atmospheric pressure. A speed-controlled dry vacuum pump evacuates the reaction vessel as fast as possible and maintains a constant low pressure at the permeate side of the membrane. A precondenser treats leakage air saturated with solvents to reduce the volume flow mainly in the beginning of the evacuation process. After compression by the dry vacuum pump solvents are partly condensed in the condenser before the stream is fed to the membrane stage and the remaining vapors are removed to a great extent. The solvent-enriched stream is recycled to the suction side of the vacuum pump, whereas the cleaned air stream is vented. Figure 18 shows a flow scheme of the process, and technical data are listed below:

Typical solvents	acetone, toluene, dichloromethane
Process pressure	atmospheric down to 1 mbar
Leakage air	up to 5 kg/h
Condensation temperature	−20 to +20°C (depending on solvent)
Solvents in vent stream:	0.1 kg/h (typical)
Power consumption	max. 10 kW at final pressure.

Figure 18. Flow scheme of vacuum drying of fine chemicals

4.7. Polyolefin Production Processes

One breakthrough of membrane-based separation of organic vapors was the introduction of membrane stages into continuous production processes. Areas of applications in polyolefin production are raw material purification, chemical reaction, and product purification, and finishing [17, 18]. Propylene, ethylene, and hexane are separated from process streams, and nitrogen can be purified and recycled for further use.

Propylene Recovery and Gas Treatment. The process objectives are the separation and recovery of propylene and the purification of nitrogen to be reused in the production plant. Propylene recovery is based on a process involving compression, refrigeration/condensation, and membrane separation.

The off-gas from the production plant is compressed by an oil-lubricated screw compressor. The discharge pressure is typically ca. 16 bar to provide sufficient driving force for the membrane separation process. The compressed process gas is released from the compressor discharge cooler at ca. 40°C and fed to a cryogenic condensation unit. A typical condensation temperature is −20°C. The residual noncondensed hydrocarbon compounds are separated by membrane separation into a hydrocarbon-depleted nitrogen stream at the high-pressure side (retentate) and a hydrocarbon-enriched stream at the permeate side. The membrane system is built as a multistage unit (Fig. 19). The first stage is typically operated with atmospheric pressure at the permeate side. To enhance the separation efficiency, vacuum can be applied at the permeate side of the subsequent stage. Finally, all permeate streams are combined to be recycled to the compressor suction.

The basic concept can be modified and the process can be tailored to specific process requirements. For instance, the number, arrangement, and operating parameters of the individual membrane stages can be adapted to optimize the overall process performance. It is also possible to employ a pressure swing adsorption unit for final polishing of the retentate stream if high nitrogen purities are required.

Polyethylene Powder Treatment. Membrane separation systems can be employed advantageously in the production of polyethylene for recovery of hydrocarbons (predominantly

Figure 19. Membrane-based propylene recovery unit

Figure 20. Flow scheme of PE powder treatment (used with permission of Basell Polyolefin GmbH)

hexane) and purification of recycle nitrogen. The membrane system is employed to treat the off-gas from the degassing bin. In this process step hydrocarbons are separated from the produced PE powder by purging with heated nitrogen. The requirements of the membrane process are:

- Purification of nitrogen for reuse as recycle gas to minimize off-gas treatment capacity.
- Recovery of *n*-hexane for reuse as feedstock in the polymerization process.
- Separation of water/acid from the recovered hydrocarbons for disposal in a suitable way.

Figure 20 shows a flowsheet of the process. Hydrocarbon-enriched vent gas from the degassing bin is fed to a quench cooler at atmospheric pressure. The cooler decreases the gas temperature from 100 to 40°C by spraying water into the suction line. The water supply is provided by the service liquid loop of the liquid-ring compression system. *n*-Hexane has negligible solubility in water. Hence, water is well suited as service liquid. The liquid-ring compressor installed downstream of the spray cooler increases the gas pressure to 7 $\mathrm{bar_{abs}}$. Subsequent to the compression stage the gas is cooled to 30°C and partly condensed. The condensate forms an aqueous and an organic (hydrocarbon) phase. The ring liquid tank also serves as phase separator from which the hydrocarbons are recycled to the overall process feedstock and water is fed to the liquid-ring compressor. The gas – vapor mixture exiting the condenser is fed via a droplet filter to the membrane modules. In the hydrocarbon-selective membranes hexane is separated from the feed gas by permeation through the membrane. The driving force of the permeation process is the partial pressure difference across the membrane. Hence, a liquid-ring vacuum pump operating at 200 mbar is installed on the permeate side to support transmembrane mass transfer. The permeate stream is recycled to the compressor inlet. The retentate stream exiting the high-pressure side of the membrane system is purified nitrogen. The stream is almost free of water, as water also permeates through the membrane and is concentrated on the permeate side. The purified nitrogen is reheated and fed to the degassing bin. Employing liquid-ring-type machinery allows for simple neutralization of the acidity of the incoming portion: aqueous NaOH solution is fed to the service liquid loop by a pH-controlled metering pump. A membrane stage for dehydration of process gas streams is shown in Figure 21. Technical data of the process follow:

Capacity	ca. 415 $\mathrm{m^3_{STP}}$/h at 1.05 bar and 100°C
Composition	ca. 500 kg/h nitrogen, 45 kg/h hydrocarbons (> 99 % *n*-hexane) 5 kg/h water
Condensation	ca. 30°C
Membrane	feed: 7 bar, retentate: ca. 6.5 bar, permeate: 0.2 bar
Power requirements	ca. 120 kW (compressor) +30 kW (vacuum pump)
Cooling water	ca. 35 $\mathrm{m^3}$/h at 25°C, $\Delta T = 5$ K
Outlet concentration	< 500 ppm hydrocarbons, < 300 ppm water
Recovery	> 99.99 % hydrocarbons

4.8. Oil and Gas Production

Natural Gas Purification. Natural gas produced at the wellhead must be treated according to the required pipeline and quality specification. Figure 22 shows the gas processing steps and the potential for membrane applications. The separation of CO_2 from gas streams has already been realized in large-scale applications [19]. Hydrocarbon dew pointing and water-vapor dewpointing of natural gas are applications of interest and have been tested in pilot scale [20].

Based on the experience gained from gasoline vapor recovery, low-pressure applications of natural gas treatment have been realized. One example is the treatment of municipal gas. Gas supplied from a public utility company was used as chemical feed stock. Because of its high content of ethane and compounds the gas must be pretreated to enhance the methane content from 86.5 to >95 vol %. The applied technique was pressure swing adsorption. Because of the high costs for replacement of activated carbon and its waste disposal, alternative technologies have been considered. The pressure swing adsorption unit was replaced by a membrane stage, as shown in Figure 23.

A single-stage membrane was installed. The separation process is supported by applying vacuum at the permeate side. The permeate stream with higher hydrocarbon content was fed to a boiler for steam generation.

If no economic use for the permeate exists, a membrane process with permeate recycling can be designed. Process optimization results in a

lower requirement of feed gas at a given product volume but an increase of membrane area and the requirement of an additional vacuum pump and recycle compressor.

Figure 23. Treatment of municipal gas to meet chemical feedstock requirements

Methane Number Control and Treatment of Associated Gas from Oil Production. The performance of a gas engine operated with natural gas is dependent on the methane number of the feed gas. The methane number characterizes the antiknock behavior of the fuel gas and is analogous to the octane number of gasoline. Figure 24 shows a pilot plant consisting of a membrane module and a vacuum pump. This plant was installed in a bypass of a feed line to a gas engine.

Figure 24. Simplified flow scheme of a membrane unit for methane number control

A methane number of 50 was sufficient for reliable operation of the gas engine. Table 3 shows the methane number enhancement at a feed pressure of 1.6 bar, a permeate pressure of 180 mbar, and a feed gas temperature of 27°C.

Membrane selectivity, installed membrane area, and available feed pressure are fixed values. Under the given conditions the increase in methane number is achieved by a reduction of feed volume flow, which is associated with an enhanced permeate flow because of the fixed membrane area. Stage cut and achieved methane number are in a direct correlation.

A comparison of alternative modes of operating the gas engine shows the following results.

Methane number	33 – 39
Calorific value of fuel gas	$H_s \approx 19\,\mathrm{kWh/m^3{}_{STP}}$
Fuel gas volume flow	$90\,\mathrm{m^3{}_{STP}/h}$
Max. power production	490 kW.

Methane number control by means of membranes:

Methane number	46 – 50
Calorific value of fuel gas	$H_s = 15\,\mathrm{kWh/m^3{}_{STP}}$
Fuel gas volume flow	$120\,\mathrm{m^3{}_{STP}/h}$
Max. power production	550 kW

To operate a gas engine with untreated associated gas the engine performance must be throttled to operate the engine in an acceptable antiknock range. The engine runs more efficiently and reliably if the methane number is increased. The engine performance and the power generation can be expanded by improved antiknock property of the fuel gas.

1. Introduction

The differences between the interactions of gas and vapor species with polymeric materials are used to accomplish gas separations and purifications with membrane devices. Figure 1 shows the relative flux rates for a variety of gases for a polyetherimide film.

The figure shows a five-decade range in the transport rates of different gases in this polymer and suggests that any number of the gas species might be separated from their mixtures due to the wide differences in their permeation rates for this polymer. These differences are unique for each polymer type. Some rubbery polymers have substantially higher fluxes than those shown in Figure 1, but these materials are typically less selective than glassy polymers. Membrane suppliers try to select polymers compatible with the application that will maximize the permeation fluxes and the selectivity for the gases involved.

Suppliers of membrane devices generally employ proprietary designs that direct the feed gas into intimate contact with a polymeric membrane surface across which the gases are separated. Besides the relative permeation rates of the species in the polymer, the feed composition, the driving force available for their separation, the membrane surface area, and the flow configuration also influence the degree of separation. The membrane device typically involves a pressure containment vessel and means for capturing permeate and retentate in ducts leaving the device. Examples of designs employed in gas separations are shown in Figures 2, 3 and 4. In Figures 2 and 3 the membrane is in the form of a flat sheet while Figure 4 depicts a hollow-fiber membrane device.

Table 1 summarizes applications and membrane suppliers. The key features of these applications are discussed below.

2. Commercial Membrane Gas-Separation Applications

2.1. Hydrogen Separation

Hydrogen is one of the more readily membrane separated gases. It has reasonably high selectivity in most glassy polymers relative to the other gas species (Fig. 1). It is also usually present in pressurized mixtures arising from the high hydrogen partial pressures employed to promote hydrogen's reactivity. Fortunately, high partial pressures are also essential for driving membrane separations. The cost of hydrogen manufacture is closely related to energy prices, since most hydrogen is produced by reforming of natural gas and hydrocarbons. There has been an ever-increasing demand for hydrogen owing largely to the higher severity in processing of heavier, sour crude oils while simultaneously reducing the sulfur content of fuel products to meet environmental regulations. Thus, the combination of technical feasibility plus environmental

and economic drivers has made hydrogen separation a major application of membranes.

Synthesis gases formed by steam reforming typically have hydrogen/carbon monoxide ratios on the order of 3/1. Adjustment of this ratio to 1/1 to satisfy the requirements of a carbonylation process [1] was the first commercial application of Monsanto's Prism Membrane technology. The application simply involves passing the 3/1 feed mixture across the membrane while withdrawing the hydrogen-rich permeate at reduced pressure. Control of the 1/1 hydrogen/carbon monoxide ratio in the carbonylation synthesis gas is accomplished under automatic process control by simply adjusting the membrane area, the feed rate, and the permeate pressure.

Hydrogenation of unsaturated hydrocarbons and hydrotreating to remove sulfur from fuels are two major consumers of hydrogen. Hydrogen supplied to reactors in these processes typically contains low concentrations of methane.

Figure 4. Axially oriented hollow-fiber module with bore and shell feeds (used with permission of Air Products and Chemicals, Inc.)

Methane and other inerts formed during hydrogenation and hydrotreating accumulate in the reactor and reduce the hydrogen partial pressure and hence the rate of the hydrogenation reaction. Thus, it is necessary to bleed off a quantity of the hydrogen reactant to purge the reactor of these inerts. Directing these pressurized purge gases to a membrane system enables a large fraction of hydrogen lost in the purge stream to be recovered as permeate and recycled to the reactor system. Inerts are thus rejected from the process at a higher concentration. The membrane system may also enable the hydrogenation to be optimized to operate at higher hydrogen partial pressures by increasing the reactor purge rate without a severe penalty on hydrogen yield. Indeed the scheme frequently enables improved throughput or quality of the hydrogenated product.

Ammonia synthesis reactions are also frequently limited by the accumulation of inerts in their reactor systems. Argon, arriving with the nitrogen reactant from air, and methane, arriving with the hydrogen, accumulate as inerts in the ammonia reactor loop. The purge from the ammonia loop is typically available in excess of 10 MPa pressure and contains more than 60 % hydrogen. Membrane systems processing this high-pressure purge typically recover over 90 % of the hydrogen. These systems typically employ two membrane units operated in series. The first recovers and recycles a large fraction of the hydrogen permeate to the final compression stage in the feed compressor of the ammonia plant, typically about 7 MPa. In the second membrane unit, the permeate is recovered at lower pressure and is recycled to the intermediate compressor stage, typically around 2.5 MPa. The rejected gas containing the concentrated inerts is typically burned as fuel in the primary reformer. The membrane systems enable ammonia plants to be optimized around higher productivity or energy savings [2 – 4]. The concentrated inerts can also be further processed by cryogenic or adsorption techniques for argon recovery [5, 6].

Methanol synthesis also deals with the accumulation of inerts in the reactor loop. In this case, the reformed gases supplied to the methanol reactor contain hydrogen, carbon monoxide, carbon dioxide, and small amounts of methane. The first three components react when the pressurized gases are circulated over the synthesis catalyst to form methanol and water. By cooling the reactor effluent gases, methanol and water are condensed and removed, leaving the methane to concentrate in the reactor circulation loop. By removing a small purge from the loop, the concentration of methane is controlled at the expense of the reactants also vented in this stream. These purged gases are available at reactor-loop pressure, typically 6 – 10 MPa, and thus have sufficient partial pressures of hydrogen and carbon dioxide to drive a membrane recovery unit. The purge gas is also saturated with methanol, a slow-permeating species that must be removed before the membrane system to avoid condensation when it is concentrated by removal of the fast-permeating species. This is accomplished in a water-scrubbing tower, the effluent of which can be combined with the crude methanol for

Figure 5. System for the recovery of methanol from hydrogen purge gas showing water-scrubbing tower (right) and membrane elements (center) (used with permission of Air Products and Chemicals, Inc.)

product distillation. Hydrogen and carbon dioxide are then recovered from the scrubbed gases in a membrane unit and recycled to the synthesis gas compressor. Figure 5 is a photograph of a purge-gas methanol recovery unit. Carbon monoxide is a slow-permeating species and therefore concentrates with the methane in the membrane reject stream that becomes fuel. Thus, as with ammonia purge recovery, the membrane unit provides efficient recovery of valuable reactants from the purge stream and provides the methanol producer with increased productivity and flexibility in plant optimization [7]. Starchem has proposed methanol production from a synthesis gas that is rich in nitrogen and contains only about 90 % of the stoichiometric amount of hydrogen needed to convert the carbon monoxide and carbon dioxide. They propose the use of a membrane unit to recover and recycle hydrogen to improve the reactant stoichiometry [8].

Hydrogen recovery systems have found similar utility in oil refining. In addition to recovery of valuable hydrogen [9], the hydrogen separation system often enables the refiner to operate at higher purge rates to increase the hydrogen partial pressure in the hydroprocessing unit. This can have a significant impact on catalyst life-

time and extend run times. It also can increase the unit's throughput and product quality. Hydrogen recovered from fuel streams can also be used to supplement hydrogen production, frequently delaying or deferring the need for added hydrogen production capacity.

Membrane processing of hydrogen-rich fuel gases can also improve the quality of the fuel gas, since the heat content of hydrogen is about one-third that of methane and higher hydrocarbons. Thus, by removing hydrogen, the heating value of the fuel gas can be adjusted to permit use of the fuel in conventional burners and equipment sized for the heating content of natural gas or even sold as pipeline fuel.

Hydrogen separation membranes are also frequently used in conjunction with other processing and separation technologies. Production of high-purity hydrogen by pressure swing adsorption (PSA) results in a waste stream containing over 40 % hydrogen. Frequently, additional hydrogen and fuel values can be realized by compression of the PSA purge and processing in a hydrogen membrane system [10, 11]. Removal of the hydrogen from hydrocarbon-rich fuel streams also enables recovery of condensable hydrocarbon liquids by processing the hydrogen-lean fuel gases in conventional expander plants.

2.2. Helium Separation

Like hydrogen, helium has high selectivity against most other components present in its mixtures for a wide variety of polymers. The primary source of helium is natural gas reservoirs, usually in concentrations below 1 %. Since low concentrations translate to low partial pressures, membranes find limited application in helium production, since multiple stages are required to reach even crude helium purities.

Membranes have found application in recovery of helium gas. Deep-diving gases employ helium mixtures that become contaminated. A combination of membranes and adsorbents are employed in purification of these gases for reuse. Small membrane systems are also employed in the purification of helium used in blimps. With time, the helium gas that inflates these lighter-than-air craft becomes contaminated with atmospheric gases. These contaminants are readily rejected by operating a small compressor and membrane unit to reject them and return purified helium to the craft.

2.3. Nitrogen Generation

Generation of nitrogen and nitrogen-rich atmospheres has become one of the largest uses for gas-separation membranes. The process simply involves passing filtered compressed air across the membrane. Since oxygen permeates faster than nitrogen, it is driven across the membrane by its partial pressure and concentrates in the permeate stream, leaving reject product enriched in nitrogen. The degree of oxygen removal is simply controlled by the residence time the nitrogen product has to contact the membrane. By reducing the product draw rate from the membrane, there is a correspondingly higher degree of oxygen removal. Thus, the oxygen concentration in the nitrogen-rich gas can be simply controlled by a process controller adjusting the product delivery rate to meet the specified oxygen concentration. Oxygen control levels vary with the application but typically fall within the 0.5 – 2.0 % range. These can typically be achieved in a single countercurrent membrane element. Concentrations below 0.1 % typically require two or more membrane elements in series [12]. Argon, carbon dioxide, and water vapor also transport readily across the membrane. Thus, the membrane-produced nitrogen is also very dry with measured dew points below −80°C.

Most nitrogen generators process compressed air at 0.7 – 2 MPa pressure and deliver the nitrogen-rich product within 0.1 – 0.2 MPa of the feed pressure. The degree of pretreatment of the air supplied to the membrane varies with the membrane employed and manufacturer. The performance of some membranes is sensitive to the moisture content of the air. In these cases, the compressed air is dried before processing. Other membranes are sensitive to organic vapors and oils, which are removed by carbon filters or absorption beds. Most generators are also supplied with filtration systems to remove condensate, mist, and any particulates that might plug the membrane flow channels or fiber bores. Since the permeability and selectivity of the membranes can be highly temper-

ature dependent, most applications require the temperature of the air feed to be controlled in order to control the quality of the product nitrogen or the membrane performance. The nitrogen product is typically delivered under pressure and flow regulation to a receiver from which it is dispensed to users on demand. The coproduced permeate is typically simply vented back to the atmosphere. The primary utility for the nitrogen is as an inerting atmosphere, typically for fire suppression. The critical oxygen concentration, the minimum level of oxygen required to sustain combustion, is typically between 9 and 12 % for many hydrocarbons and organic compounds. Thus, maintaining oxygen below 3 % provides ample safety margin for many inerting applications. These levels can readily be reached with membranes having oxygen/nitrogen selectivities greater than 4. Thus membrane-generated nitrogen finds ready application anywhere flammable materials are stored, processed, or handled. Storage in a low-oxygen atmosphere also preserves many fruits, vegetables, and produce. A low-oxygen atmosphere, typically in the 2 – 10 % range, depending upon the produce, is required. This is readily accomplished by purging the storage atmosphere with nitrogen or a nitrogen-rich gas as supplied by a membrane generator.

Membrane-based nitrogen generation equipment is supplied by a number of manufacturers (Table 1). Most are industrial gas suppliers who also use the equipment to supply smaller gas sales accounts. Membrane units are also used to supplement nitrogen supply at larger scale of gas accounts. Frequently, the membrane units are sized to handle a continuous, base-load requirement with truck-supplied liquid nitrogen providing backup and covering peak demand. Many of the membrane manufacturers also market membrane modules to original equipment manufacturers (OEMs). The OEMs incorporate the membrane modules and nitrogen generation capability into their own packaged equipment offers. Since compressed air is necessary for nitrogen generation, many OEMs are also compressor manufacturers and air-compressor distributors. Other OEMs are specialty equipment manufacturers whose equipment is dependent on a nitrogen supply. For example, a manufacturer of metal-processing furnaces often incorporates inert-atmosphere generation as part of his offer. Similarly, an instrument manufacturer may incorporate a small nitrogen generation system in his package to free his product from dependence on laboratory or cylinder nitrogen supply. Their features of portability, light weight, compactness, and robustness have aided in their incorporation into nitrogen-generation packages that literally can operate on land, at sea, or in the air. Some of the applications served by membrane nitrogen-generation equipment follow.

Shipboard Inert Gas. Nitrogen generated onboard ships is used to purge the vapor space in vessels containing liquid chemicals or flammable hydrocarbons on chemical tankers, the seals on cryospheres on LNG tankers, and various electronic systems on navy ships.

Controlled Atmosphere Storage. Membranes are used to maintain controlled atmospheres in warehouses for perishables, cargo containers, and the holds on banana reefer ships.

Tank and Process Equipment Inerting. Many offshore platforms, marine terminals, refinery and chemical tank farms are supplied with membrane-generated nitrogen.

Industrial Gas Sales. Many membrane suppliers are owned by or affiliated with industrial gas companies. They use on-site nitrogen generators to supply nitrogen to meet customer demand from base load to total-site nitrogen requirements, frequently supplemented with liquid nitrogen supply or backup.

Laboratories, Photo Processors, etc. Many facilities have replaced nitrogen cylinders with small wall-mounted cabinets that generate nitrogen for laboratory use from compressed air.

Metals Processing. Membranes generate nitrogen for inerting many sintered-metal process furnaces, soldering station blanketing, and the like.

Tire inflation. Flight line ground support carts generate and store high-pressure nitrogen for inflating aircraft tires and struts. Tire molding operations and truck and automobile service centers are supplying compressed nitrogen in place of compressed air for tire inflation to reduce tire oxidation and improve tire life.

Figure 6. Typical membrane performance for acid gas removal from mixtures with methane or nitrogen (used with permission of Air Products and Chemicals, Inc.)

Oil and Gas Field Service. Membrane-produced nitrogen is replacing air in pneumatic drilling, used in oil well servicing, and for pipeline purging.

Flare and Seal Purging. Small nitrogen generators supply seal gas to a variety of seals on rotating machinery. They also supply purge to flare piping systems.

On-Board Inert Gas Generation System (OBIGGS). In the U.S. Air Force F-22, a small bleed of compressed air from the jet engine's turbine compressor is processed into nitrogen to purge the fuel tanks onboard the aircraft. OBIGGS is gaining increasing interest for military and commercial aircraft with the discovery of a fuel tank explosion as the probable cause of the TWA Flight 800 disaster.

2.4. Acid-Gas Separation

Figure 1 shows that the acid gases carbon dioxide and hydrogen sulfide have permeabilities in polyetherimide film that are about 20 times those of methane, nitrogen, and carbon monoxide. The latter are species that frequently accompany acid gases in mixtures of commercial interest. Commercial acid gas removal applications include production of pipeline-grade natural gas [13, 14], carbon dioxide recovery and recycle in enhanced oil recovery (EOR) [15 – 17], methane recovery from landfill and biogas [18, 19], and carbon dioxide recovery from flue gases [20, 21].

The performance of a typical acid gas removal membrane is shown in Figure 6. This graph provides operating lines for several feed compositions and predicts combinations of permeate and nonpermeate product composition

that can be produced when the membrane feed-to-permeate pressure ratio is greater than 20. Inspection of this diagram reveals the dilemma associated with membrane applications for acid gas separations, namely, that it is difficult to produce high purity products in either the permeate or the nonpermeate at high recoveries with a single membrane stage. Thus, it is necessary to have an alternative application for the impure coproduct, or resort to a more complicated process involving compression of the permeate to feed successive membrane stages to achieve high degrees of separation [22]. Study of the diagram reveals that processing a typical raw natural gas to a pipeline-grade natural gas containing less than 2 % carbon dioxide while rejecting carbon dioxide at greater than 90 % purity would require at least three membrane stages with permeate compression between each stage. The economy for such makes it practical in only a limited number of applications.

Despite this limitation, membranes are finding increasing application in acid gas removal. The successful applications depend upon identifying utility for the low-purity coproducts in another service or application. For example, processing a feed with 20 % CO_2 to pipeline-grade natural gas produces a medium-heating-quality fuel that is used for power generation. In another case, a membrane unit produces a high-CO_2 permeate gas suitable for injection into an oil reservoir for enhanced oil recovery, while the coproduct is processed further in a conventional amine sweetening process.

2.5. Gas Dehydration

The capability of membranes to dry gases was recognized in the early hydrogen, acid gas, and nitrogen membrane applications. Indeed some nitrogen generation systems were marketed for their ability to produce a very dry product suited for purging of cryogenic and LNG equipment. It was recognized early that a membrane's productivity of dry gas was dependent upon the creation of sufficient permeate volume to maintain the very low partial pressure driving force associated with a product containing only parts per million of water. Monsanto introduced the Cactus membrane air dryer in 1987, which relied on a different, higher flux membrane on the dry-product end of the separator [23]. This allowed a portion of the dried product to be used as a countercurrent sweep gas to create a good partial pressure driving force for the permeating water along the dryer length. Other dryers have since been introduced by a number of suppliers that rely on a four-ported membrane design as shown in Figure 4 to provide a controlled amount of sweep gas.

Most membrane dryers such as the Cactus Membrane Air Dryer line shown in Figure 7 are marketed to OEMs and compressor and instrument distributors. These devices process filtered, compressed air to deliver dry, compressed air having dew points as low as −40°C at 1 MPa pressure.

Figure 7. Cactus membrane compressed air dryers (used with permission of Air Products and Chemicals, Inc.)

Using membranes for drying natural gas was suggested as early as 1984 [24], but it was 1996 before the concept became reality when Air Product's Permea organization introduced a swept dryer design that was capable of drying gases to pipeline specifications at absolute pressures as high as 7 MPa [25]. Since then several

demonstration units with capacities as high as 200 KNm^3/d have been installed.

The high-pressure dryer has also found application in high-pressure compressed air systems onboard U.S. Navy vessels [26]. These dryers are typically operated between compressor stages at absolute pressures of 30 – 70 MPa and the dry product returned to the next compression stage for final boost to the 20 – 33 MPa receiver pressure.

3. Developing Membrane Applications

3.1. Oxygen and Oxygen-Enriched Air

All nitrogen generators necessarily produce an oxygen-enriched air (OEA) coproduct, but it is generally vented to the atmosphere. This is probably because the OEA is at low pressure, varies in composition due to process controls on the nitrogen generator, and volumes are small in comparison to meaningful OEA application requirements. One commercial application generates OEA for use in intermittent catalyst regeneration. This application is unique though as there is also an on-site application for nitrogen generation. Membranes have also been employed to produce OEA for ozone generators. Most attempts have involved the OEA coproduct from compressed-air-driven nitrogen generators. Since ozone generation is proportional to oxygen concentration and is favored by atmospheric-pressure operation, feeding the OEA to an ozone generator would appear to be a logical application. However, the economics are highly dependent on recovering value from the nitrogen coproduct stream. The application involves feeding the membrane with dry compressed air, since any moisture present in the feed copermeates with the OEA and interferes with ozone generation.

Only a small amount of the oxygen supplied is converted in an ozone generator. In a typical application, the ozone-rich stream is processed in an absorber or contactor tower to decompose organics in waste streams. Vent gases leaving such equipment are rich in oxygen, and thus there has been interest in their recovery and recycle to the ozone generator. Air separation membranes have been operated in such a recycle arrangement to enrich the OEA to as high as 60 – 70 % oxygen. At these levels, the ozone generator becomes very effective and more than doubles in productivity over an air feed. Such is the good news. Unfortunately, any residual ozone in the vent gas recycle stream also attacks the polymer membranes. With time, even ppm levels of ozone have a cumulative, irreversible, degrading effect on the membranes and shorten their useful life. Design of guard beds, ozone-destroying catalysts, and the like to protect the membranes have been successful during normal operation, but control systems designed for low ozone levels were not sufficiently responsive in detecting and responding to overload and upset conditions before damage to the membranes in the demonstration unit.

OEA production from air is favored by vacuum-driven membranes operating at low oxygen recovery. In this case, the OEA purity is simply a function of the membrane's selectivity and the vacuum level at which the OEA permeate is withdrawn. Unfortunately, the high selectivity membranes employed in nitrogen generators have low flux and would require huge membrane areas at subatmospheric pressure. Presently, high-flux materials are being used, but OEA purities are limited to less than 30 % oxygen. There is much research activity in pursuit of higher flux, more selective membranes that will bear watching for this application.

3.2. Nitrogen-Enriched Air (NEA)

Compact Membrane Systems is actively pursuing NEA as a replacement for exhaust gas recycle (EGR) as an NO_x abatement measure on diesel engines. The CMS membrane with its high flux and low selectivity is capable of enriching the turbocharged engine air to 81 – 84 % nitrogen. Such levels have been demonstrated as being effective in substantially reducing NO_x in the diesel engine exhaust [27].

3.3. Nitrogen Rejection from Natural Gas

A number of membrane developers and suppliers are pursuing nitrogen rejection from natural

gas with high-flux, low-selectivity membranes. Modest nitrogen depletion (30 – 50 % nitrogen removal) in the pressurized natural gas has been demonstrated at a beta site with plasma-treated polydimethylsiloxane membranes supplied by Neomecs [28]. Permeate from the nitrogen depletion membrane unit is nitrogen-enriched. As in the cases of acid gas removal discussed above, this application also depends upon the disposition of this low-energy gas.

3.4. Carbon Dioxide Removal from Liquid Hydrocarbons

Cynara [29] has recently piloted a membrane process for removing carbon dioxide dissolved in liquid ethane. Minor amounts of carbon dioxide in the natural gas feed to a turbo-expander plant can accumulate in the natural gas liquid (NGL) products. The Cynara membrane pilot processed the reflux to a de-ethanizer column. Driving force for carbon dioxide removal was provided by routing fuel gas for a process-fired heater to the sweep-gas side of the membrane. Adjustment of the sweep flow rate enabled 40 – 50 % of the carbon dioxide to be removed, thereby maintaining the contaminant concentration below the 6 % specified in the liquid ethane product.

3.5. Removal of Condensable and Volatile Organic Compounds (VOC)

A number of membrane suppliers have introduced membrane products for recovery and removal of hydrocarbons, VOCs, and condensable organic compounds from process and vent gases. Silicone membranes can separate many condensable hydrocarbon and organic vapors from noncondensable gases such as methane, nitrogen, and air. This is enabling them to be piloted and employed in a growing number of small applications. GKSS's membrane is being used to recover gasoline and fuel vapors from storage tank vent gases. Membrane Technology and Research (MTR) has demonstrated the utility of a silicone membrane in NGL recovery and dewpoint control in natural gas processing and in fuel gas conditioning for gas turbines and engines.

Compact Membrane Systems is developing a VOC recovery process based on their perfluoropolymer membrane. Unlike silicone membranes, which transport the hydrocarbon liquids, CMS's copolymer of perfluorodimethyldioxole (PDD) and tetrafluoroethylene (TFE) allows the noncondensable gases to pass through the membrane and rejects and concentrates the condensable hydrocarbons.

1. History

Marine fuels for diesel engines cover a wide range of different grades, ranging from gas oil fractions often referred to as “distillates” —and including a grade with properties similar to automotive diesel fuel— to heavy residual fuel oils containing refinery residues remaining after crude oil distillation. While the distillate fuels are mainly used in the smaller high-speed engines (speed higher than 1000 rpm), the residual fuel oils are used in the large-bore, low-speed cross-head engines (below 350 rpm) and also in medium-speed engines.

For a long period marine diesel engines were solely fueled with the distillate type of fuels. Only after World War II the potential use of heavy residual fuels was investigated. These fuels with densities up to 1000 kg/m^3 and even above and viscosities up to 700 mm^2/s at 50 °C were originally used only as boiler fuels for steam generation. The low cost of these residual fuels was an incentive to investigate their use also in the large marine diesel engines. However, initially the cost saving obtained was more than offset by the increased difficulty in fuel handling and treatment (heating and separation of unsuitable material) and even more significantly by the higher rates of engine wear and additional maintenance cost. This situation changed dramatically after the so called “oil crises” in the 1970s. After that time the fuel cost increased and also the gap in the differential cost between the higher quality distillate fuels and the residual fuels widened, followed by a general move to the cheaper heavier fuels especially in the low- and medium-speed marine engines.

The higher fuel cost required also an improvement in the overall efficiency of the marine propulsion systems. As the diesel engine offered more scope (by approaching 50% total efficiency) than the steam turbine, an increasing number of new ships were equipped with diesel engines fitted with the treatment systems (mainly heating systems and centrifuges) required for the use of heavy residual fuel grades.

2. Specifications

While initially only fuel specifications by the suppliers existed, the need of international specifications was recognized with the increased use of heavy fuel oils in diesel engines. For that reason the British Standard BS MA 100 was introduced in 1982, followed by the ISO Standard 8217 in 1987. Furthermore there is an ASTM Standard D 975 and a diesel engine manufacturers and users specification issued by the International Council on Combustion Engines (CIMAC) and published first in 1986.

The ISO Standard 8217 specifies four distillate fuels (see Table 1), the three lighter ones DMX, DMA and DMB, to be used without specific fuel treatment on board, and 15 residual fuels, which require heating to reduce their viscosity and also generally centrifuging to separate water and foreign matter before their use in the engine (Table 2).

Table 1. Requirements for marine distillate fuels

Characteristic	Limit	Category ISO-F-				Test method reference
		DMX	DMA	DMB	DMC	
Appearance		Visual		–	–	See 6.2[5]
Density at 15°C, kg/m^3	max	[1]	890.0	900.0	920.0	ISO 3675 or ISO 12185 (see also 6.3[5])

[Top of Page]

3. Composition

The hydrocarbon composition of marine diesel fuels depends mainly on that of the crude oil used in the refinery (e.g., distillates and distillation residues have compositions controlled by the crude oil) but also on the secondary refinery process units, e.g., aromatics content when the highly aromatic catalytic cracker cycle oil is used as a component in the residual fuels. Whereas the distillate fuels consist mainly of alkanes and cycloalkanes (i.e., paraffins and naphthenes), alkenes (olefinic hydrocarbons), and aromatics, the residual fuels contain also asphaltenes. These are very large hydrocarbon molecules with a very high carbon/hydrogen ratio and have complex, mainly aromatic structures and molecular masses between about 5000 and 40 000. In a stable residual fuel, that meets the standards described in Chapter Specifications, the asphaltenes are colloidally dispersed. Depending on the crude oil, the oil molecules contain also oxygen, sulfur, nitrogen, metals such as vanadium, chromium, nickel, aluminum and other nonhydrocarbon atoms in low concentrations.

When a paraffinic crude oil is used to produce a residual fuel oil often an aromatic diluent (such as cat cracker cycle oil) must be added in the refinery to prevent agglomeration of the asphaltene molecules and avoid sludge formation.

Long-chain alkanes in residual fuels may be present to some extent in form of wax at ambient temperature. Care must be taken to avoid precipitation and formation of waxy sludges during storage.

The residual fuel oils may also contain impurities such as water, sand, rust from tanks and pipelines, and catalyst fines from refinery processes, which must be separated prior to the use in the engine to avoid unacceptable wear in fuel pumps, injectors, and cylinder liners. The chemically bound sulfur present in marine diesel fuels (in the heavier grades up to 5%) require the use of specific highly alkaline cylinder lubricants to avoid corrosive wear.

[Top of Page]

4. Properties

Distillate Fuels. The specification of the lightest distillate fuel DMX is basically similar to that of automotive diesel fuel, however, DMX has no density and no distillation limits. These parameters are indirectly controlled by viscosity and cloud point. The minimum ignition quality (cetane number) of DMX is lower than that of automotive diesel fuel and the maximum sulfur content is higher. This distillate fuel is also referred to as an emergency fuel, because it can be used without any treatment on board down to low temperatures. The remaining heavier distillate fuels DMA (also referred to as gas oil), DMB, and DMC, have higher maximum density, viscosity, and sulfur levels, whereas low-temperature fluidity and cetane number are reduced. The more viscous fuels are geared to the requirement of medium-speed engines with longer piston strokes, offering more time for the air-fuel charge to ignite and burn during the combustion cycle and hence the ignition performance (characterizing ignition delay after injection and ease of combustion) of the heavier fuels is less important. The heaviest distillate fuel DMC may contain traces of residual fuel oils and therefore specification criteria used in that fuel category to control impurities such as water, vanadium, and aluminum/silicon have been added.

Residual Fuels. The 15 residual fuels RMA 10 to RML 55 are grouped according to viscosity, their numbering being identical with the viscosity at 100°C, rising in steps of 10 mm^2/s with one intermediate fuel of 15 mm^2/s. Each viscosity group contains either two or three fuels, allowing different concentrations of asphaltenes described by variations in, e.g., densities, carbon residues, or vanadium content. Fuel manufacturers' specifications use often the viscosity at 50°C and their fuel denotations thus differ from that used in ISO 8217. In the traditional marine business the viscosities at 50°C are still the most widely used viscosity parameters.

While initially the maximum density of the fuels was restricted to about 0.990 kg/m^3 to guarantee the separation of water by centrifuging, modern centrifuges can safely handle fuels with densities even above 1000 kg/m^3 and for that reason the maximum density of some of the more viscous fuels was raised to 1010 kg/m^3.

The flash point (safety aspect in storage tanks) of all residual fuels is identically specified to be ≥ 60°C. In theory the fuels should not produce ignitable air-fuel mixtures in the fuel tank atmosphere below this temperature.

Paraffinic wax formation at low temperature is controlled by specification of the pour point. The pour point is 3°C above the temperature at which the fuel will not flow under its own weight when tested by standard methods. The pour point is a guide for low temperature filterability/pumping limits and wax precipitation in storage tanks. (In automotive diesel fuel the cold filter plugging point, CFPP, a low-temperature filterability test, has shown better correlation with low-temperature fuel filterability performance). As residual fuel oils are heated anyway to reduce their viscosity, wax formation even with the high pour points of 30°C causes generally no problems. However, care must be taken that the fuel is not cooled and heated in cycles around the pour point, because under these conditions wax formation may increase. It should be noted that some paraffinic wax crystals once formed in residual fuel oils have melting temperatures approaching 100°C.

Ignition performance of residual fuels is not specified, because there is sufficient time in the low-speed – long-stroke engines to burn even highly aromatic/asphaltenic fuels with low ignition performance. It was also shown that engine and operating parameters (e.g., fuel viscosity when injected, charge temperature and pressure) can compensate fuel deficiencies in this aspect. When changing from one fuel to another, it may, however, be necessary to rank their ignition performance. It is well known that that the ignition performance of a diesel fuel decreases with increasing aromatic content. In the absence of both, a suitable and simple test method of ignition performance and of aromaticity of residual fuels, the Calculated Ignition Index (CII) and the Calculated Carbon Aromaticity Index (CCAI) have proven useful. Both methods use fuel viscosity and density as parameters. Increasing viscosity and density simultaneously increases the aromatic content and reduces the ignition performance. At a given density reducing viscosity and at a given viscosity increasing density increases the calculated aromatic content and reduces the ignition performance of the fuel. Details are described in an appendix of ISO 8217.

The carbon residue of marine diesel fuels is measured to estimate the coke forming and fouling tendency of a fuel. It is generally related to the asphaltene content, but there are considerable differences in this relationship between different fuels. The correlation of carbon residue with formation of deposits in marine engines is poor and that is not surprising because modern marine engines (specifically low- and medium-speed engines) are built to operate safely with fuels of high asphaltene contents and high carbon residue. However, the carbon residue has been retained in specifications to characterize the fuel.

The ash content of fuels is specified, because inorganic ash-forming matter, either of natural origin or originating from contamination, can form deposits in the turbocharger and in the engine.

Specifically deposits on the exhaust valve seats can lead to valve burning and finally failures. Whereas insoluble and water-soluble material (e.g., rust and sodium salts from sea water) are generally removed by fuel centrifuging, “natural” oil-soluble ash-forming impurities (mainly various metals and silicon), which tend to concentrate in the distillation residues, cannot be separated on board.

Water is the most common contaminant of marine fuels. Water content is often increased after delivery in the ships fuel tanks, either because of leakage into the tank or by tank breathing and condensation. Water bottoms in fuel tanks can lead to rust formation and to the growth of fungi in the water-oil phase. This may cause additional sludge in storage tanks. Fuel centrifuging separates most of the water before the fuel is supplied to the engine.

Sulfur is a natural constituent of crude oil. It is chemically bound to the hydrocarbon molecules and the sulfur concentration varies depending on the crude oil source, ranging from about 0.1% (e.g., Nigerian crude) to nearly 3% (e.g., Venezuelan crude). In distillation residues, used for the blending of residual fuels, the sulfur content is even higher. Heavier grades may contain a maximum of 5%. During combustion the sulfur is converted to sulfur oxides. Together with the water formed by combustion the sulfur oxides form sulfuric acids, which may cause severe corrosion of cylinder liners and piston rings. By the use of highly alkaline cylinder lubricants and higher engine temperatures to avoid condensation, the engine wear problem has been largely overcome, however, there remains the emission of sulfur oxides with the exhaust gases. The use of high-sulfur fuels is therefore restricted or penalized in some coastal areas.

Also vanadium is—like sulfur—a natural trace constituent of crude oil. During combustion vanadium together with sodium may produce in a series of complex reactions sticky and low-melting salts, which may adhere to exhaust valves and turbochargers, causing high temperature corrosion. Apart from restricting the concentration of vanadium in residual fuels there are operational (reduction of exhaust valve temperature) and metallurgical (specific alloys) solutions to avoid this type of corrosive wear.

Aluminum and silicon in fuel oils stem from disintegrated cat cracker catalyst. Of course these catalyst fines may only be present when cat cracked components are used as components. The catalyst fines may cause abrasive wear. Below the specified limit of 80 mg/kg they are safely reduced by centrifuging to uncritical levels.

The total sediment contains not only inorganic insolubles but, after aging of the fuel, also insoluble organic fuel components such as agglomerated asphaltenes. As mentioned above, residual fuels contain significant amounts of asphaltenes which are kept finely dispersed by aromatic diluents. Fuel stability tests are main criteria of quality control in refineries and it is unlikely that any stability problem producing asphaltenic sludges occur with fuels supplied from refineries according to in-house and international standards. However, if a fuel is blended with paraffinic diluents or fresh asphaltenes are produced by heating (e.g., with electrical heaters with too high skin temperature), it is possible that the asphaltene/aromatic ratio is altered and the asphaltenes may agglomerate adding considerably to sludge formation. Experience has shown that residual fuels with total sediments below the specified 0.1% can be handled without any problems with the standard centrifuging equipment.

Another important quality criterion, which is not specified, is the fuel’s specific energy. The specific energy can, however, be calculated sufficiently precisely from the inspection properties of the fuel, if known. For details see ISO 8217. Increased density (i.e., higher carbon/hydrogen ratio), sulfur and, of course, water and ash content reduces the specific energy on a weight basis (in MJ/kg). However, fuels belonging to the high density/viscosity categories have usually lower prices, their deficiency of lower specific energy content is therefore generally more than offset by the price.

[Top of Page]

5. Outlook

While for several decades fuel research and engine development was geared to reduce overall cost by improving efficiency and engine life with cheap fuels, the focus has changed to improved environmental acceptability. In the area of marine diesel emissions this is mainly the reduction of harmful exhaust gas constituents. Depending on the nature of these pollutants there are different options, i.e., changes in fuel composition, of the combustion process, or exhaust-gas aftertreatment. Different technologies are available and have partly been proven “on shore” such as selective catalytic reduction (SCR) exhaust-gas aftertreatment catalysts to reduce nitrogen oxides. Research in all three areas is ongoing, however cost and practicability on board are some of the limiting factors. International standards on emissions taking into account the technical potentials with acceptable lead times or penalties, as already enforced in sensitive areas like the Baltic sea, help to neutralize the cost factor and will lead to environmentally improved ship propulsion systems.

Performance measurement is a competitive tool widely used by manufacturing and service organizations to evaluate the output of business processes. Its fundamental purpose is to quantify the potential for improvement and construct plans for further development. This article aims to increase the understanding of performance measurement in chemical plants. Existing performance measurement practices are reviewed, and their roles in the improvement of business and operational results of chemical process plants are defined. A developed performance measurement model, called the "operational effectiveness model", is also introduced. It comprises a sequence of several performance measurement steps which ensure that chemical batch plants operate efficiently and effectively.

1. Introduction

Performance measurement is a competitive tool and it has been widely used by manufacturing and service organizations to evaluate the output of business processes. The fundamental purpose of performance measurement is to quantify the potential for improvement and to construct plans for further development [1 – 3]. The recognition of the importance of performance measurement in manufacturing and the need for linking manufacturing strategy and performance measurement can be traced back to a specific article [4]. Since that article, the number of strategic-oriented performance measurement tools has increased, but selecting the right one is a real chal-

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.k06_k01

lenge. This selection difficulty is caused by the variation between different manufacturing processes, a dissimilarity of business objectives, and the depth of understanding of specific business requirements.

Performance measurement is used to evaluate, control, and improve a company's production process, to ensure the achievement of its goals and objectives. If results differ from objectives, an organization can analyze the gaps in performance and make adjustments. Performance measurement is also used to compare the performance of different companies, plants, and individuals. In addition, performance measurement provides a means of capturing performance data, which can be used to inform decision making [5].

It is contended [6] that measurement plays a crucial role in translating business strategy into results. In a survey of top U.S. companies [6], it was found that companies with effective measurement tend to anticipate the future and are likely to remain competitive in a radically changing environment. Performance measurement yields many benefits for an organization. One benefit is that it provides a structured approach to focus on a company's vision, strategy, goals, and performance. Another benefit is that it provides a mechanism to report program performance to high-level management. Besides, performance measurement can help companies [7]:

- Track progress in achieving desired performance goals.
- Control performance within predetermined boundaries.
- Identify problem areas and possible problem causes.
- Show where improvement needs to be made.
- Ensure that decisions are based on fact, not on emotion.
- Identify whether suppliers are meeting requirements.
- Compare and benchmark competitors' performance with their own.
- Set future targets.
- Drive change.

World-class manufacturers are at the top of their industries as a result of their consistent delivery of superior performance [1, 8, 9]. This superior performance is achieved by continual assessment and improvement of business processes, application of the proven best solutions to improve the performance of key business areas, and continual measurement of financial and operational performances [1, 10, 11].

The application of performance measurement practices produced a tool called "benchmarking". Rank Xerox defined this [12] as "a continuous, systematic process of evaluating companies recognized as industry leaders, to determine business and work processes that represent best practices, and establish rational performance goals. There are four types of benchmarking [12]:

- *Internal benchmarking* applies more to large organizations that have various business units. It is about comparing internal operations from one sister company to another.
- *Competitive benchmarking* specifically compares competitor to competitor, using the product or function of interest. This goes beyond traditional product or service engineering, but it is important to learn and understand about competitors' methods, their processes, innovation, strategies, markets, etc.
- *Functional benchmarking* is the comparison of similar functions within the same broad industry, using wide industry leaders as partners.
- *Generic benchmarking* involves establishing the comparison of business functions or processes that are the same, regardless of type of industry. Generic benchmarking is a long-term challenge and reflects a total change in the culture. It is usually found in learning organizations.

The fact that process industries are less familiar with measuring and benchmarking their own process manufacturing performance has been discussed in the literature [1]. The argument often used for why this unfamiliarity occurs is that the process industries are different; therefore, the implication is that performance measurement and benchmarking techniques do not apply [1]. These techniques, however, have been developed and successfully applied in other manufacturing industries such as electronics, retail, and automotive.

This article aims to increase the understanding of performance measurement in chemical plants. The objective is to assist these plants in their journey to attain effectiveness in op-

erational performance. In this article, the existing performance measurement practices are reviewed, to define their roles in the improvement of business and operational results of chemical process plants. A developed performance measurement model, called the "operational effectiveness model", is also introduced. The model comprises a sequence of several performance-measurement steps that are put together to ensure that operations at chemical batch plants are operating efficiently and effectively.

2. Performance Measurement Practices

Companies in manufacturing or service normally define objectives from their manufacturing mission and vision [13], then define and implement their manufacturing strategies to attain these objectives [14]. The objective is the statement of a general condition that needs to be achieved and the strategy was defined as "the art of devising or employing plans toward a goal" [15]. The strategy to attain the performance objectives often requires the selection of some appropriate tools that can drive the actual performance of the process towards the levels of performance targets (benchmarks) to ensure that the process is operating effectively. The performance measurement system is used to assess the output results of the adopted strategies, with respect to customer expectations and strategic objectives [4, 12, 16 – 18]. As suggested [19], however, such measurements will be more useful if they can also serve as a diagnostic aid to better understand the reasons why a company is performing well or poorly; therefore, a well-designed system of performance measurement must incorporate the ability to both monitor and diagnose performance. The performance measurement system is often constructed as in the performance measurement system design process [13]. The performance measurement system, however, is a constructed framework comprising different elements, such as how performance would be measured, which area or activity in the process should be measured, and which measures and which type of performance targets would be used. It is stated [20] that good systems include the need to link operations to strategic goals, integrate financial and nonfinancial information, measure what is important to customers, motivate operations to exceed customer expectations, and identify and eliminate waste.

It is said [21] that an effective performance measurement system should consist of not only the traditional financial and cost-accounting criteria used by upper management, but also tactical-performance criteria that are used to assess the firm's current level of competitiveness and direct its efforts to attaining a desired competitive position. The roles of performance measurement can be categorized into three aspects:

1) It provides the company with a method to assess its current competitive position with respect to its competitors and the demands of the market and identify avenues for improvement.
2) It monitors the company's progress in moving towards its strategic objectives [13].
3) It highlights where improvements have been made and which areas still need to be improved [22].

In Sections 2.1, 2.2, and 2.3, the performance measurement frameworks, performance measures, and target setting methods are briefly described for the purpose of highlighting requirements for measuring results of adopted strategies and attaining the objectives of chemical plants.

2.1. Performance Measurement Frameworks

Several performance measurement frameworks were developed to assist practitioners and researchers in measuring the performance of organizations in the manufacturing or service sectors. It was stated [23], that the first development of the "tableau de bord" performance measurement system was carried out in the early 1900s, by a group of French engineers. In the last three decades, however, several performance measurement frameworks were introduced, such as the strategic measurement analysis and reporting technique (SMART) [20]; the balance scorecard [24]; the performance prism [25]; and the hierarchical performance measurement system [26]. These performance measurement frameworks proved to be effective tools for measuring the performance of organizations and also

assisted businesses to shift from focusing on traditional financial results, to focusing on new dimensions related to employees, customers, and other stakeholders. These frameworks are found to be useful for application at different levels in the organization, as they provide management with a complete set of performance data to inform decision making. They are, however, lacking the details required by engineers on how to define targets, tackle causes of poor performance, define improvement areas, and implement best practice.

A methodology was presented on how to measure and benchmark the performance of process manufacturing plants [1]. Several categories of performance measures were defined for this purpose. These categories of performance measures are customer services; reliable assets; operational excellence; motivated people; and safety, health, and environment. This methodology has also recommended the use of fewer focused measures, to make the process more effective. Another approach, called the "manufacturing enterprise performance measurement system", was introduced [11]. It is a top-down approach for the manufacturing organization, in which the organization's objectives, strategies, and performance measures are identified at different levels of the organization. By applying the methodology of benchmarking performance of the process plants in the manufacturing enterprise performance measurement system, it was found to be useful for measuring the levels of plant, department, or business in the organization, but bottom-line operational levels are difficult to measure by this methodology, as this level requires specific techniques to define performance targets and demonstrate performance results. The operational level at the plants requires a framework that can handle the technical details of the operations and actions of the bottom line process and identify proper performance targets, based on the capability of the process.

2.2. Performance Measures and Key Performance Indicators

Manufacturers are required to provide their products to users at the expected time, with reasonable prices, and meeting the required quality [27]. As a result, several performance measures are used in practice and research, to give an indication of the performance of process plants, as well as plants from other manufacturing sectors. Traditionally, the measures used to evaluate a company's performance have been based primarily on conventional accounting systems. Examples of these measures include earnings per share, inventory turns, return on investment, purchase price variance, labor efficiency, and machine utilization. Such measures are focused on local measures of efficiency and productivity [5]. Among them, productivity and cost are the most frequently used measure of manufacturing performance. Manufacturing companies monitor employee productivity, facility output, and direct and overhead costs, for a variety of time frames. This is because only costs are available and easy to measure [28]. The purpose of financial accounting measurement [29] is to report the company's activities to interested parties outside the company, whereas a company's cost accounting measure is supposed to provide information useful to managers' planning and control decisions. Financial accounting measures, in general, would provide managers with knowledge of the system performance that reflects the results of past decisions, but not the actionable steps needed for surviving in today's competitive environment.

As a result of the limitations of the traditional performance measures, attempts have been made to develop a set of better-balanced measures that would provide management and operators with the on-time information that is necessary for daily decision making [30]. Such measures should be flexible, primarily nonfinancial, and able to be changed as needed [31]. A major benefit of nonfinancial measures is that they can usually be reported on a timelier basis than financial measures. As a consequence, if a nonfinancial measure indicates poor performance, action can often be taken before negative financial consequences occur. In addition, nonfinancial measures are easy to understand and are always available. This provides instant feedback regarding the performance of the company [32].

The key performance indicator (KPI) is one type of performance measures. The KPI is a number, or value, which can be compared against an internal or external target performance benchmark, to give an indication of per-

formance. That value can relate to data collected or calculated from any process or activity [33, 34]. The KPIs are often classified as strategic-in-nature KPIs or operational-in-nature KPIs. Operational KPIs are used by managers to plan and control programs at operational level, while strategic KPIs provide guidance to both managers and policymakers who have to make decisions from a more global perspective. Generally, KPIs should be selected according to how they relate to the strategic aims of the organization and how they can support the corporate-level performance indicators. This means that KPIs, whether they are operational or strategic in nature, must tie in to strategy.

In general, in chemical batch plants, there is still a requirement for operational measures that can support achieving the required level of performance in the strategic KPIs.

2.2.1. Corporate Performance Indicators

Corporate performance indicators are related to achievement of corporate objectives; some of these performance indicators are sales growth, customer loyalty, assessment of stakeholders' satisfaction, percentage market share, profitability measures, return on investment (ROI), return on capital employed (ROCE), and return on net asset (RONA).

Customer loyalty is a qualitative performance measure, ranging from "never buying from anywhere else because the experience is so satisfying" to "returning, because there is no alternative available".

Sales growth can be calculated from self-reported data (Eq. 1).

$$\text{Sales growth} = \frac{(\text{Total sales this year} - \text{Total sales last year})}{\text{Total sales last year}} \quad (1)$$

Sales figures do not necessarily indicate how a firm is performing relative to its competitors. The firm's performance relative to competitors can be measured by the proportion of the market that the firm is able to capture. This proportion is often referred to as the market share (Eq. 2).

$$\text{Market share} = \frac{\text{Firm's sales}}{\text{Total market sales}} \quad (2)$$

Firms that have high customer loyalty usually have a high market share in their defined markets. Market share is often associated with profitability; thus, many organizations seek to increase their sales relative to competitors.

The return on investment (ROI; Eq. 3) is a measure used to determine whether a proposed investment is required and how well it will repay the investor.

$$\text{ROI} = \frac{\text{Profit}}{\text{Investment}} \quad (3)$$

Return on capital employed (ROCE; Eq. 4) is probably the most popular ratio for measuring general management performance in relation to the capital invested in the business. ROCE defines capital invested in the business as total assets less current liabilities.

$$\text{ROCE} = \frac{\text{Net profit before interest and taxes}}{\text{Total capital employed}} \times 100 \quad (4)$$

Return on net assets (RONA; Eq. 5) is another measure of financial performance. The higher the return, the better the profit performance for the company.

$$\text{RONA} = \frac{\text{Net income}}{\text{Fixed assets} + \text{Net working capital}} \quad (5)$$

With regard to shareholder value, the key driver is profit, or the expectation of profit.

2.2.2. Strategic Key Performance Indicators

Several key performance indicators are often used to measure the strategic performance of manufacturing processes. The "adherence to production plan" (Eq. 6) is the main key performance indicator for the effectiveness of manufacturing processes to meet production planning. It is the percentage of planned activities on the sales and operations plan (S& OP) that are completed as planned in a planning period [1]. Deviations from the plan are sometimes caused by equipment failures or by poor demand forecasting. This key performance indicator indicates the opportunities for improving the demand management process [1].

$$\text{Adherence to production plan} = \left(1 - \frac{\text{Actual production} - \text{Forecast production}}{\text{Forecast production}}\right) \times 100 \quad (6)$$

Overall equipment effectiveness (OEE; Eq. 7) was developed in the 1980s [35]. This key performance indicator measures the effectiveness of equipment's deployment to perform work over a period of time:

$$\text{OEE} = \text{Performance rate} \times \text{Quality rate} \times \text{Availability} \quad (7)$$

The production losses, as defined by the OEE, are related to equipment breakdown, setup, minor stoppage, reduced speed, scrap rate, and startup. Many batch and continuous plants in the chemical industry have used OEE to measure the performance effectiveness of their operations and have used the results to tackle the causes of low performance and optimize outputs. The main criticism of OEE, however, is that all the measured losses are equipment-related losses.

The process capability (CpK) [1], is the flexibility and quality key performance indicator. It measures the encountered variability of process results without effect from any special cause (Eq. 8)

$$\text{CpK} = \frac{\text{Lower of (upperspec} - \text{average)}}{3\sigma} \quad (8)$$

where upperspec is the upper level of allowable deviation from the average, and σ the standard deviation.

The on time in full (OTIF; Eq. 9) is the supply chain's main key performance indicator. It measures the percentage of all deliveries that are delivered to the final customer on the mutually agreed date and location, defect-free in all respects. This includes the product quality, order size, packing, and support paperwork [1].

$$\text{OTIF} = \frac{\text{Number of defect-free on-time shipments}}{\text{Total number of all shipments}} \quad (9)$$

The stock turn (Eq. 10) is a financial key performance indicator. It is an important KPI for internal issues and also needs to be as high as possible, to ensure that the capital is not tied up on inventory.

$$\text{Stock turn} = \frac{\text{Cost of sales}}{\text{Values of all materials in stock}} \quad (10)$$

The value of all materials in stock comprises the value of raw materials, work in progress, finished goods, and engineering items. The reasons for holding stock are many and varied [1]. It could be strategic stock in anticipation of some process or plant unreliability, or a change in the world supply market; financial reasons, where any significant price rises are anticipated and the products have been bought ahead of this; stock may be held due to process unreliability, in anticipation of planned shutdowns, or in consignment form to ensure that the customer is never let down. Hence, stock turn may be used as a measure of customer service or operational excellence.

The value added per manufacturing employee (Eq. 11) is also a financial key performance indicator. It is the value of sales turnover, from which all goods and services purchased are subtracted, divided by the number of direct employees working in manufacturing [1].

$$\text{Value added per manufacturing employee} = \frac{\text{Value of sales} - \text{all costs of the production}}{\text{Number of manufacturing employees}} \quad (11)$$

The KPIs described above are considered as a strategic level set of measures [11]. The sequence of these KPIs, however, gives a complete set of strategic performance measurements, related to different strategic dimensions. The appropriate combination of measures is determined by the nature of the actual industry. A bulk chemical industry, for example, may focus more on the adherence to sales and operational planning (S& OP), whereas a consumer product industry is encouraged by its final customers to pay particular attention to issues such as OTIF and customer complaints. In general, these KPIs support the corporate performance indicators at the corporate level of the organization, such as return on investment, return on assets, market share, customer loyalty, stakeholder satisfaction, and so on.

2.2.3. Operational Key Performance Indicators

Operational KPIs are often selected with respect to their relevance to the operational objectives and the strategic KPIs. Some of the commonly used operational measures are as follows:

- *Manufacturing cycle time*: the total time that the process takes, from start to finish, to produce the required product. This time normally comprises the time required for cleaning, loading, processing, and emptying the equipment.

- *Value of stock in warehouse*: all the money the system invests in purchasing things the system intends to sell.
- *Cost reduction*: KPIs in this category measure the achieved cost reduction through an improvement programme.
- *Amount of wasted materials*: material losses from processing, quality control inspections, handling, and transfer of materials.
- *Quality measures*: these measures comprise right-first-time performance, defects per unit of production, and detailed pareto diagrams, etc.
- *Equipment uptime*: uptime is defined as the time a process operates at its standard maximum proven rate while making a defect-free product. The ratio of uptime to the total available time is often calculated by Equation 12.

$$\text{Uptime}=\frac{\text{Valuable operating time}}{\text{Valuable operating time}+\text{Total losses}} \quad (12)$$

- *Equipment downtime*: downtime is defined as the period when the equipment is not available to fulfill its intended role. Downtime can consist of planned activities, such as scheduled maintenance, repair, and overhaul, and unplanned activity as a result of a failure or accidental damage.
- *Resource utilization* is defined as the proportion of time that a resource is used.
- *Final product yield*: for a description of this measure, see Section 3.1.4.2.
- *Production capacity* is defined as the maximum rate of output that a production unit is able to produce under a given set of operating conditions.

The basis for calculating operational performance measures, however, differs from one sector to another, from plant to plant, or even from one operation to another operation within the same plant. The manufacturing cycle time is an example, as, in some cases it may be calculated by simple, straightforward equations, or in other cases, may require complicated calculations.

2.3. Performance Targets for Chemical Process Plants

The target is the level of result that needs to be achieved. The purpose of performance measurement is therefore to compare actual performance results with an established set of performance targets [36]. There is still little attention paid to this area, in terms of definition and explanation of effective methods, to define the performance targets for performance measures. It was stated [37] that many companies have a problem when performing benchmarking activities. This problem is caused by a difficulty in retrieving quantitative data relevant to world-class or competitors' performances. It was also highlighted [37] that there is little work being done to address this problem or, at least, to propose a dynamic technique that can help manufacturing organizations in this area. When data for benchmarking are not available, the organization is advised to establish targets the best it can [37]. Organizations have always set performance targets and used measurement systems to track the achievement of targets [17, 18, 29, 38]. The targets were classed in four categories [29]:

- *Competitive benchmarking*: in this category, a detailed analysis is made of competitors' operations and an attempt is made to emulate the best aspects of each competitive company.
- *Price targeting*: this category includes the application of cost-control techniques in detail, throughout the initiation and design phases of a new product. This programme results in a detailed breakdown of cost and quality targets for each department of the company.
- *The half-life concept*: this category includes an analysis of the rate of improvement that can be expected for different kinds of continuous improvement tasks. This system provides a more objective method of setting goals for quality improvement programs.
- *Common sense and a world-class manufacturing mind-set*: this category includes the application of realistic and motivating targets for companies involved in the introduction of world-class manufacturing techniques and continuous improvement.

Four methods that can be used to set or generate performance targets were also defined [17, 18]:

- *Historical targets*: this method is often used, owing to its simplicity in implementation [39]. The best historical performance of an activity would be defined, then used as a performance target.

- *External targets*: by using this method, the world-class performance of best-in-class operations is collected to use for benchmarking purposes. Table 1 lists some superior performances of process industries' world-class plants that are often used as performance targets. Importing external benchmarks from competitors' performances, however, is often an essential requirement for competitiveness in any business.
- *Internal targets*: these targets are based on comparisons of the performance of internal processes. In this method, the performance of the best performing process in the company is used as a benchmark. This method is myopic, however, in the sense that it looks only within the organization and may limit the company's performance relative to its external environment [39].
- *Theoretical targets*: in this method, the targets are determined by the use of theoretical calculations, or by simulation analysis. Setting performance targets on a theoretical basis is exceptionally useful, as it defines the performance capability and limitations of the process. A considerable disadvantage of this method relates to the difficulty and time needed to define it. The theoretical targets of the process would enable effective comparisons of process performance to benchmarks from external sources; they would help in assessing the capabilities of operations and whether or not they are able to perform similar to best-in-class operations.

Table 1. World-class performance of process plants [1]

No.	Key performance indicator	World-class performance
1	Adherence to production plan	> 99 %
2	Overall equipment effectiveness (OEE)	> 95 % for continuous plants> 85 % for batch plants
3	Process capability (CpK)	> 2
4	On time in full (OTIF)	> 99.9 %
5	Stock turn	> 25
6	Value added per manufacturing employee	$400 000
7	Training days per employee	12 d
8	Absenteeism	< 1 %

2.4. Performance Measurement Problem in Chemical Process Plants

The continuous mode of operating process plants has, to some extent, fewer management problems at operational levels. The equipment in this mode is designed and scaled to produce bulk chemicals with a defined rate of production. In addition, most material-handling and -moving steps are automated. In this case, defining the ideal performance target is not a difficult task; therefore, applying the operational, or strategic KPIs in the plant is rather simple, when compared to the batch process plants.

In the case of batch mode, performance measurement often encounters some problems. In this mode of production, for example, flexibility in the product formulation and production rate causes uncertainties when selecting an optimum set of operation variables. The manufacture of different products in the same production equipment will also require frequent changeover and equipment setups. Consequently, cleaning at the changeover between two different products causes the loss of a significant amount of materials. A further problem is that the flexibility achieved by batch processing, which enables the production of larger or smaller quantities, also raises the question of the cost effectiveness of the selected size of the batch.

Despite the fundamental improvements made by applying manufacturing practices to the performance of manufacturing plants, there is still scope for improvement in chemical batch processes, as new tools are needed for defining a complete set of performance measurement requirements. Therefore, research, in such areas as defining performance objectives, defining manufacturing strategies, and defining elements of performance measurement system, is fundamentally important to chemical batch plants.

2.5. Performance Objectives of Batch Chemical Plants

The manufacturing objectives of the batch chemical plants were defined by a review of relevant research literature and on informal interviews with some key individuals in batch chemical plants. The conclusion of the study was that

the minimum production cycle time, maximum yield of final product, and minimum total production costs are the main three objectives of the batch chemical processes [18, 40, 41].

There are several benefits of cycle-time reduction, some being minimum waste in time, cost reduction, increased flexibility, efficient employees, and less time exposed to risk while operating hazardous processes.

The main benefit of increasing the yield of the final product is the utilization of raw materials. Raw materials make up the largest portion of manufacturing costs; therefore, when they are used inefficiently, waste will be created, which will lower sales revenue and create an environmental problem [42].

Economic batch quantity is an essential requirement to achieve the minimum cost of manufacturing. Capacity decisions are vital to the manufacturing plants, as they affect a number of dimensions in the business, such as delivery date, product prices, and warehouse requirements. Costs associated with production setups, resource utilization, and inventory holding are all related to the batch quantity and contribute to total manufacturing costs. The link between stock and the financial performance of organizations is strong [43]. The organizational objective "maximizing return on assets" is a good example of this link. Another advantage of manufacturing at economic batch quantity is the tuning of the output of manufacturing either to meet only the market demand, or to produce for demand and inventory. Therefore, when the manufacturing process is optimized for minimum cycle time and maximum yield, then the economic batch quantity will ensure that the plant will not overproduce to meet the objective of those two factors.

In Chapter 3, a detailed model is introduced, showing how to measure performance of the chemical batch plants with respect to the three performance objectives.

3. Operational Effectiveness Model

This chapter of the article introduces the operational effectiveness model as a performance measurement tool for chemical batch plants, as shown in Figure 1. The proposed model is developed from the framework introduced in [18]. The steps of this model are discussed in terms of how they are developed for the specific requirement of manufacturing in chemical batch plants. This high-impact model is planned to be capable of developing tools for industry, to redefine their operational effectiveness requirements.

Figure 1. The operational effectiveness model for measuring performance of a batch chemical process.

3.1. Structure of Operational Effectiveness Model

The model begins with the development of an understanding of manufacturing process inputs and the fundamental requirements that are placed on them. In another concurrent step, the pertinent performance measures must be identified, which in this case is the introduction of a new key performance indicator, called the "batch effectiveness factor" and its calculation requirements. Next, the model's actual manufacturing process is defined concurrently, and ideal performance targets are determined. Performing comparisons, performance analysis, and a signposting route for improvement steps, are also included in the model.

3.1.1. Step 1: Manufacturing Process Inputs

The process inputs are key elements in the manufacturing process that will influence its perfor-

mance. The process inputs must be selected to meet certain standards, such as the specification of raw materials, skills of operators, reliable equipment, adequate scheduling, and the right sources for process utilities. All these requirements are process inputs, or resources, that are required in the majority of manufacturing processes. These inputs would interact with each other in performing the required product with the required quality, time, and amount. Information from external stakeholders must be collected and analyzed for any requirements that may be included in the process. Sources of external requirements could include downstream customers, governmental organizations, or labor unions. Customer requirements placed on the manufacturing process will often include factors related to product quality, price, and delivery date.

3.1.2. Step 2: Effectiveness Measures

The selected performance measures in this model are: effectiveness of cycle time, specific yield, and effectiveness of capacity. The three measures are single performance measures for defining performance of the batch process. Each of them measures the process with regard to one performance objective. The performance effectiveness of the process in relation to each objective is calculated by comparing actual performance of the process to the performance targets (Eq. 13).

$$\text{Performance effectiveness} = \frac{\text{Actual performance value}}{\text{Target performance value}} \times 100 \quad (13)$$

The results of the three performance effectiveness measures are then combined in one factor, called the *batch effectiveness factor*, which gives an indication of the effectiveness of the batch process, in relation to the three objectives, as shown in Equation 14.

$$\text{Batch effectiveness factor} = \text{Cycle time effectiveness} \times \text{Specific yield} \times \text{Capacity effectiveness} \quad (14)$$

The development of the batch effectiveness factor aims at unifying the results of performance effectiveness with respect to the three objectives in one factor. Performance assessors therefore can determine whether the process is achieving thorough effectiveness without being misled by the value of effectiveness in meeting one objective.

3.1.3. Step 3: The Actual Process

The process is the main part of manufacturing; therefore, the process step is set as the core of the operational effectiveness model. In the process, the actual inputs and resources are transformed to create the required product. The utilization of resources is often a crucial issue for many manufacturing enterprises. In an ideal manufacturing operation, the processes would operate at full utilization of all resources, for example, full utilization of manpower and equipment time, full utilization of capacity, zero waste from handling and processing of raw materials, and no scrap from the process utilities. This situation, however, is rare in real operations. The difference between the ideal and the real situation is due to losses [17, 18]. Based on the adequacy of inputs, resources, tools, and the extent of utilizing inputs or resources, production of the required product will either meet or deviate from the required performance targets, and hence the performance objectives. Any output of the process is expected to be a product, byproduct, or waste. Increasing the value in the finished product or minimizing the amount of unwanted byproduct, material waste, wasted time, and manpower requirements would result in an increase in the desirable outputs [44].

3.1.4. Step 4: Theoretical Determination of Performance Targets

The targets used in the calculation of effectiveness measures, as defined by Equation 13, will become the subject for the theoretical definition of the ideal performance of batch processes. Mathematical calculations, taken from the science of each selected operation or action in the process, will be used. The theoretical model for generating a performance target would represent the behavior of the process as it manufactures a batch from start to finish. Such a view would provide the necessary information for the

creation of a simulation model of a batch process, which would include routing information, process times, and, among others, labor requirements. The actual input data will be used in the calculation of the theoretical targets. The generated ideal results will be tested for their practicality; if the results are satisfactorily accepted, then they can be chosen to become the process performance target. The approach of theoretical performance targets is an attempt to provide an answer to the fundamental question "what must the process do?". There is an understanding that the route towards the achievement of world-class level of performance is through the full knowledge of the level of results that can be obtained from the process.

In some cases, the model aims to investigate the heat-transfer steps in chemical plants, to predict the time needed for achieving the required heating or cooling. In chemical engineering literature, a procedure exists for prediction of heating or cooling requirement for the chemical batch process [45 – 47]. Another aim is to study chemical reactions in the chemical process and develop kinetic models for them. The variables affecting the rate of the chemical reaction require investigation, using laboratory and plant based data, with the aim of achieving maximum yield of the final product in a minimum cycle time. In the literature, there are also procedures to predict the time for materials mixing, separation, crystallization, and transfer. Generally, the determination of theoretical targets, intended for the operational effectiveness model, will include procedural examples of how to define the cycle time for selected operations in the process, defining the yield of the final product and defining the economic batch quantity.

3.1.4.1. Determination of Ideal Cycle Time

The measurement of cycle time is a primary feature of performance measurement for world-class manufacturers [29]. Ideal cycle time is the minimum time that a process takes from beginning to end, ideally without shutdowns or production-speed slowdowns. This ideal cycle time can be supplied in the nameplate by equipment manufacturers, derived from calculations, or obtained from a simulation of the process [18]. Some process operations and actions need theoretical investigations to assess the possibility of reducing their time and use of the ideal results as performance targets. These operations and actions include, for example, heat transfer, chemical reaction, material transfer, mixing, and separation.

3.1.4.1.1. Prediction of Heat-Transfer Time

The measurement and control of energy use within processes are interrelated, essential aspects of good energy management (→ Energy Management in Chemical Industry). The heat-transfer steps in the process require detailed theoretical study to predict the time frame for achieving the required heating or cooling. The prediction of heat-transfer time is required at the preliminary stages of the process equipment design, to assist the estimation of total process time and the required amount of energy to generate heating or cooling. Mathematically, for the chemical batch process, there is an existing procedure, related to the prediction of heating or cooling requirements [45 – 47]. Equation 15 is used to calculate the quantity of transferred heat Q from or into the system [48 – 50]. This equation is derived from Fourier's Law [51] and, when used for the batch reactor, the only variables are overall heat transfer coefficient U_o and the logarithmic mean temperature difference ΔT_{LMTD}, as the heat-transfer area A in the batch reactor is constant. The main drivers of improvement in the time needed for heating or cooling are therefore U_o and ΔT_{LMTD}. A higher value of U_o will decrease the heat-transfer time; therefore, a maximum value of U_o is needed for the objective minimum cycle time.

$$Q = U_o \, A \, \Delta T_{LMTD} \tag{15}$$

Properties of the equipment's material of construction, physical and chemical properties of the process and service fluids, and the operational conditions are the main factors affecting the value of U_o. Choosing raw materials with the right physical and chemical properties will assist in operating the chemical plant efficiently. The main physical properties affecting the performance of heat-transfer operations are viscosity, specific heat capacity, thermal conductivity, density, and specific gravity. Operating conditions such as flow rate of heat-transfer fluid and

temperature difference between the heat-transfer fluid and process fluid also play important roles in determining the value of U_o.

3.1.4.1.2. Chemical Reaction Cycle Time

The reaction rate is dependent on the reaction order. In this situation, the rate of a first-order reaction is directly proportional to the concentration of a single reactant [52, 53], and that of a second-order reaction increases as the square of that concentration [52]. In batch chemical processes, kinetics of the chemical reaction are needed in order to specify the type of reactor to be used (→ Process Development) and estimate the required time for the process, for use as a parameter in the design of plant equipment and also to estimate the profitability of the process. The variables affecting the rate of chemical reaction are temperature, concentration of reactants, surface area of reactants, pressure, presence of a catalyst, phase of reactants, presence of inhibitors, and equipment configuration [52, 53]. In the literature, the effect of such issues on increasing the rate of the chemical reaction has been discussed intensively. The optimization of the rate of chemical reaction is based on those issues and, in many cases, would result in a significant improvement of reaction time. Many research efforts were carried out to minimize the chemical reaction time for different processes. Generally, kinetics of the chemical reaction are critical to estimating the required time for the process, but detailed kinetic models, or mathematical optimization methods, are still seldom utilized in the industry to determine the optimal operation policy. Instead, a simple trial-and-error method and subsequent product quality check is preferred when deciding on the best operating policy [54].

3.1.4.2. Defining Ideal Yield

Manufacturers aim to obtain a high yield from each manufactured batch. The target is to achieve the highest potential transformation of raw materials into a desirable finished product. The existing definition of yield in the field of chemical engineering has limited improvement practice to the chemical reaction, or the transformational steps. Different definitions of yield and selectivity are indicated [55], and when reading literature on chemical reactions it is advisable to check carefully to ascertain the definition intended by the author. In the definition of yield [56], care must be taken to allow for the stoichiometry of the reaction. A decision must also be made whether or the yield should be calculated relative to the amount of reagent introduced into the system, or relative to the amount of reagent consumed. Work on the operational effectiveness model will relate to the yield of the whole process, in order to facilitate the definition of certain areas for improvement and to increase the desirable outputs. The effectiveness of the manufacturing process can be determined by calculation of the specific yield (Eq. 18).

The actual yield, theoretical yield, and specific yield can be defined [1, 41, 57, 58] as follows:

Theoretical yield y_{At} is the ratio of maximum potential amount of desired product to the ratio of all material inputs (Eq. 16).

$$y_{\mathrm{At}} = \frac{\text{Maximum potential amount of desired product}}{\text{Total amount of raw materials fed to the process}} \quad (16)$$

Actual yield y_{A} is the ratio of actual amount of produced desired product to the total amount of all material inputs (Eq. 17).

$$y_{\mathrm{A}} = \frac{\text{Actual amount of desired product}}{\text{Total amount of raw materials fed to the process}} \quad (17)$$

The specific yield y_{Asp} is the ratio of actual yield to theoretical yield (Eq. 18).

$$y_{\mathrm{Asp}} = \frac{\text{Actual yield}}{\text{Theoretical yield}} = \frac{y_{\mathrm{A}}}{y_{\mathrm{At}}} \quad (18)$$

The theoretical yield is a useful performance target for the actual process to aim at. The specific yield would then approach or reach 100 % — a value which is extremely difficult, if not impossible, to achieve [41], as the maximum amount of product is rarely produced. Product may be lost in material transfer, as a byproduct, or by inadequate operating procedures.

3.1.4.3. Defining Ideal Production Quantity (Economic Batch Quantity)

Manufacture at economic batch quantity is a strategy that is often used to attain the objective of minimum manufacturing costs [42, 59 – 61].

Measuring economic batch quantity is not new in science or practice, but it is rarely seen in chemical plants. Chemical batch plants produce to full equipment capacity for the following reasons:

1) Full utilization of equipment capacity and resources (Process Development)[55].
2) Safety inventory of finished products [1].
3) Concerns about the life cycle of liquid chemicals as raw materials.

With the emergence of world-class manufacturing practices and, in particular, the just-in-time (JIT) philosophy, the concept of full capacity utilization has been under intensive investigation, in order to compare savings from the utilization of resources during the production process and inventory costs. Following this, the concept of "economic batch quantity" was introduced into production planning and scheduling. The economic batch quantity (EBQ) is the quantity of production that operates at minimum total manufacturing costs (Eq. 19) [62]

$$\mathrm{EBQ}=\left(\frac{2C_{\mathrm{o}}\,D}{C_{\mathrm{H}}}\right)^{1/2} \tag{19}$$

where C_{o} represents batch-quantity-sensitive production costs, C_{H} inventory holding costs, and D inventory consumption rate.

The batch-quantity-sensitive production costs comprise the setup costs and costs of resources that are sensitive to batch quantity. The cost of holding inventory is known as the carrying cost and consists of warehousing, insurance, funds required, spoilage, and obsolescence.

Alternatively, the economic batch quantity can be determined as shown in Figure 2; in which the point for minimum total cost identifies the economic batch quantity.

Equation 19 and Figure 2 are explained in some detail in several textbooks [42, 59 – 61].

3.1.5. Step 5: Import of External Benchmarking Data

Performance of best-in-class operations is difficult to import at the batch level in chemical batch plants [11, 17, 18, 63]. This, however, should not delay efforts to collect the external benchmarking data. A comparison with other internal processes, or with other plants that have the same process, is also a useful option. A step in the operational effectiveness model has therefore been created to allow external benchmarks to play a role.

Figure 2. Defining economic batch sizes

Generally, care should be taken when using theoretical targets, as they are not enough in themselves; the competition may have deployed better equipment, technologies, or innovations to generate high-performance results. It is therefore advisable to use different target-setting methods in conjunction, as none of these methods are adequate, individually, for determining performance targets.

3.1.6. Step 6: Comparisons and Identification of Gaps

In Steps 3 and 4 of the operational effectiveness model, the actual and ideal performances of the manufacturing process were defined. The objective of performance targets is to compare the actual performance to them. In this case, the actual and optimum values of performance are defined, to give an indication of the process effectiveness, that is, close the actual performance is to its target. Each actual performance measured in Step 3 in the model is compared to the theoretical performance target determined by Step 4 in the model, to determine the effectiveness measures using Equation 13. At this stage in the operational effectiveness model, the batch effectiveness factor can be calculated, and then the gaps in the financial performance can be estimated. The batch effectiveness factor considers complicated optimization procedures to generate ideal performance results, its equation is simple and easy to use. Generally, the batch effectiveness

factor can track the growth of a performance gap, as it can be measured at any time and for any operation in the process, provided there is an ideal performance target for that operation; therefore, this key performance measure can work online during the processing of the batch and give real-time results. If a gap starts to appear, an immediate improvement measure can be taken to alleviate the performance deviation; there is no such characteristic in other performance measures.

3.1.7. Step 7: Definition and Application of Improvement

Practices that are used to achieve ideal performance are needed, in order to define the required improvement actions. When poor performance is detected, the role of these practices is to define what actions should be taken to improve performance. Following that, the process engineers of manufacturing plants are encouraged to identify and analyze the requirement for improvement that exists among multiple performance alternatives, with the aim of closing the gap in understanding the effect of chemical engineering concepts in performance results. This model aims to close this gap by defining the process parameters by which the performance is influenced. Basic concepts are needed to understand the interaction between materials, equipment, and control parameters, such as temperature and speed of processing. Analytical techniques are also required to demonstrate an understanding of the ways to prevent failure to meet performance targets.

Below are some of the best manufacturing practices, utilized by world-class companies to meet increasingly demanding customer expectations and continually improve operating performance.

- *Lead Time Reduction*: world-class manufacturers are measuring and continually reducing manufacturing lead times. Time of non-value-adding steps in the manufacturing process is eliminated or minimized, to increase manufacturing velocity and therefore increase value to customer.
- *Process Reliability*: manufacturing improvement practices are in place to maximize equipment uptime and reduce variation in product quality. Effective methods and tools are also used for quick changeover, to improve equipment availability performance, and respond quickly and efficiently to changes in schedule and customer needs. Operating procedures and quality standards are consistent and manufacturing improvement practices are used to ensure sustainability.
- *Process Modeling and Simulation*: process modeling and simulation are used owing to two main needs [64, 65]: to gain better understanding of a specific process and to reduce the range of experimental work required for process development.
- *Performance Measurement*: key performance indicators and shop-floor goals are in place for each area, developed at the operating level and tied directly to plant goals.

Generally, operational performance excellence in each of the above areas will give the plant a real competitive edge.

3.2. Example of Practical Application

Two batch processes from a specialty chemicals plant are selected to evaluate the applicability of the developed operational effectiveness model. The actual field data of cycle time, yield, and batch quantity were monitored and recorded for manufacture of products A and B. Observations highlighted some bottleneck process steps in the process cycle time and also identified significant amounts of material waste during the handling and transfer of materials in these two processes. The bottlenecks in the cycle time steps were found mainly in the time needed to heat or cool the batch to the required temperature. Transfer of material has a subsequent longer time. The calculated results show that heat-transfer time, mixing, and material addition can be reduced significantly by the use of optimum operational conditions. Further, the time spent by samples in quality control can be eliminated by using online sampling techniques. The use of overhead tanks to reduce material addition time in the case-study plants has little support from the point of view of this research, as the cleaning process of the equipment is expensive and time-consuming. In addition, due to some exothermic reactions, some of the material requires a slow rate of addition, so the use of overhead

Table 2. Results of potential improvement in performance

	Product A		Product B	
Measure	Actual	Theoretical	Actual	Theoretical
Cycle time, h	12.24	6.39	9	5.2
Yield, %	92.2	94.7	97.36	100
Batch quantity, drums	17	varies	17	varies
Batch effectiveness factor, %	50.6	100	56.3	100

tanks will not decrease the time of addition in some steps of the process. The theoretical yield was also defined for the two manufacturing processes. The two values of the theoretical yield of both products showed that there are significant amounts of waste; this will affect the value of the actual yield. At the manufacturing plant, efforts are needed to eliminate the source of these material losses and increase the amount of product. Economic batch quantities at different assumed inventory consumption rates were calculated. The results showed that the financial gap will increase each time the difference between the actual and economic batch quantity increases. The effectiveness measures and the batch effectiveness factor were calculated; hence, financial analyses are performed, in order to evaluate performance gaps and the potential for improvement. As shown in Table 2, defining the actual performance for each effectiveness measure and defining the theoretical performance targets made it possible to calculate the batch effectiveness factor for the two processes. The financial gaps related to these values of the batch effectiveness factors are significant. These gaps in the operational and financial performance can still be closed, by eliminating the causes of performance gaps. The optimum performance was determined, but in this case was based on the available specifications of the system and the materials. These optimum results may improve further if a better system or raw materials were used.

The batch effectiveness factor proved to be an appropriate performance measure for the batch process at the chemical plant. Application to the selected case-study plant revealed significant losses in time, materials, and money in the existing actual processes; these losses can be eliminated by definition of the operational performance objectives and adoption of the operational effectiveness model, as defined in this article. The developed tools showed the improvement value, in terms of providing an understanding of how lower level performance improvements can have impact on a firm's ability to achieve its objectives. The improvement in the process time and yield of the final product caused an increase in the financial value of the product, thus creating financial savings. The improvement in the total cycle time of the process and the final product yield also supported excellent performance of the manufacturing plant. These improved results led to flexibility of operations, improved delivery performance, and less exposure to the hazards associated with the chemical processes. The achieved improvements will therefore result in the improvement of strategic KPIs, such as adherence to the production plan, OEE, OTIF, and value added per manufacturing employee. Consequently, the strategic KPIs at the top level of the manufacturing company will be supported and rise to the levels of performance excellence.

4. Conclusion

This article has introduced the requirement that a manufacturing organization needs to measure performance in chemical plants. Performance measurement frameworks, different categories of measures, target setting methods, and how to solve particular problems related to performance measurement are described. Defining the effective performance of operations in the chemical plants is vital, in order to achieve success in manufacturing businesses. To increase the effectiveness of operations within these plants, however, it is imperative that there is an understanding of the relationship between performance and the achievement of objectives. Development of new tools is also needed to assess the performance of the operation in chemical batch plants. In this context, the operational effectiveness model in this article was developed. It comprises a new

key performance indicator, called the "batch effectiveness factor", and the use of theoretical procedures to define performance targets. Defining the theoretical targets as optimum states of the process was found to be supportive to management, to define the routes to attain their objectives, investigate the root cause of any deviation, and understand the financial significance of being at the level of best-in-class operations.

Epothilones represent a novel class of anticancer drugs which inhibit the cell cycle by interfering with microtubules. Their chemical and pharmacological properties as well as several synthetic approaches to some of the natural compounds are described.First results from clinical trials with natural epothilones as well as novel derivatives are promising indicating that epothilones have the potential to become a cornerstone in future cancer therapy.

1. Introduction and History

In 1991, the first two members of a new class of natural products (epothilones A and B) were described in a patent application by the groups of HÖFLE and REICHENBACH [17]. Both compounds were isolated from the myxobacterial strain *Sorangium cellulosum* originated from a soil sample collected in the bed of the Zambesi river in South Africa. Beside several potential uses as plant protecting or antifungal agents, also their cytotoxic or immunosuppressive properties were claimed.

In 1995, BOLLAG et al. at Merck Research Laboratories reported that epothilones exert their high antiproliferative activity by the stabilization of microtubules. Up to this time, taxanes had been the only class of compounds addressing this type of mechanism (see → Cancer Chemotherapy, Chap. 7). However, in contrast to taxanes, epothilones possess the ability to maintain their cytotoxic activity also in tumor cells that have developed marked resistancies against widely used therapeutic agents like Taxol® or anthracyclines. A better water solubility of epothilones compared with that of taxanes offers higher flexibility for the development of formulations that avoid the use of cremophore to which is attributed the amplification of side effects of Taxol®. Beside these potentially beneficial aspects, the most potent natural compound epothilone B still displays significant toxicities at therapeutically relevant doses that result in a narrow therapeutic window. Therefore, an epothilone analog possessing an improved therapeutic window would be highly desirable for clinical applications. The development of such a compound has stimulated intensive research activities in chemistry, pharmacology, and medicine [18, 19].

2. Physical Properties

Epothilones A to F are solids. They are well characterized by different methods such as ^{1}H and ^{13}C NMR, UV, IR, and mass spectrometry. Some physical properties are given in Table 1. Epothilones B and D are commercially available.

Stability. The pure compounds are quite stable but it is recommended to store the compounds at lower temperature (−20 °C to 4 °C). In solution, the stability depends on the pH. Under basic conditions, the lactone ring is opened,

in acidic solutions the epoxide can be cleaved by hydrolysis.

The metabolic stability of epothilone B has been intensively studied. Lactone and epoxide hydrolysis is the most prominent metabolic pathway [20].

Figure 1. X-ray structure of epothilone B

Epothilones are 16-membered macrocyclic lactones containing two hydroxyl groups, one carbonyl group, and a *Z*-configurated double bond which can also be oxidized to an epoxide. Attached to this ring system is an unsaturated side chain bearing a thiazole. From these molecular features, the name EPOTHILONE was created: EPOxide, THIazole, LactONE. The compounds possess 7 to 8 stereogenic centers and are isolated in optically pure form. The relative and absolute configuration of epothilones A and B (Fig. 1) as well as their three-dimensional conformation were undoubtedly confirmed by X-ray crystallography [21, 22].

The chemical structures of epothilones A to F are shown in Table 2. Beside the IUPAC nomenclature, an alternative numbering became generally accepted which is depicted for epothilone D as an example (Fig. 2). This counting is also applied for the epoxide containing epothilones and will be used in the following description of the syntheses too.

Figure 2. Epothilone D with alternative numbering

3. Syntheses

A large number of total syntheses have been described in numerous review articles and monographs [2 – 5, 12, 15, 16]. Common to each approach is a modular and highly convergent synthesis based on different building blocks. Beside the natural compounds, these strategies also allow the preparation of various analogs. The methodologies developed by the different research groups have found entry into the industrial development.

In Table 3, four different strategies to construct the 16-membered macrocycle are outlined. Exemplarily, a synthesis will be described for each strategy.

Table 2. Chemical structures of epothilones A to F, their CAS numbers, and IUPAC names

Structure	Name, CAS No.	IUPAC name
	epothilone A[*152044-53-6*]	(1*S*,3*S*(*E*),7*S*,10*R*,11*S*,12*S*,16*R*)-4,17-dioxabicyclo[14.1.0]heptadecane-5,9-dione, 7,11-dihydroxy-8,8,10,12-tetramethyl-3-[1-methyl-2-(2-methyl-4-thiazol-yl)ethenyl]

Figure 4. Synthesis of fragment C1-C6

Synthesis of fragment C1-C6 starts from commercially available propane-1,3-diol in which one hydroxyl group is selectively protected (Fig. 4). After the remaining hydroxyl group has been oxidized to aldehyde **2**, a chain elongation with the optically pure borane **3** yields the chiral alcohol **4**. After formation of the acetonide, the double bond is cleaved to give aldehyde **5**, which is transformed via a Grignard reaction followed by an oxidation to the desired fragment **6**.

Synthesis of fragment C7-C12 is achieved by a diastereoselective alkylation of **9** followed by reductive cleavage and subsequent oxidation (Fig. 5). Compound **9** is obtained from reaction of the chiral auxiliary **7** with the acid chloride **8**.

Figure 5. Synthesis of fragment C7-C12

Synthesis of fragment C13-C15 starts from the known aldehyde **2** already used in the synthesis of fragment C1-C6 (Fig. 6). Grignard reaction with **11** generates the racemic alcohol **12** from which the optically pure compound **13** is obtained via a kinetic resolution procedure according to Sharpless. Silylation and oxidative cleavage of the double bond yields ketone **14** which is subjected to a Wittig-Horner type reaction with phosphonate **15**. Selective deprotection of the primary silyl ether gives alcohol **16** that is oxidized to the aldehyde and subjected to a further Wittig reaction to form the desired fragment **17** after desilylation.

Figure 6. Synthesis of fragment C13-C15

Now, compounds **6** and **10** are connected in an aldol reaction by which two additional stereocenters are generated with high stereoselectivity (Fig. 7). After the acetonide is removed, triol **18** is persilylated. The most labile primary silyl ether is selectively cleaved and the resulting alcohol oxidized to the carboxylic acid **19**.

To complete the carbon skeleton, acid **19** is esterified with alcohol **16** to give the ester **20**. The formation of the 16-membered ring is accomplished using the ring-closing metathesis (RCM) as key reaction yielding a 1:1 mixture of the *E*/*Z* double bond isomers in a total yield of 94%. After separation, the protecting groups in **21** are removed to give epothilone C. Stereoselective epoxidation of the double bond furnished epothilone A along with minor amounts of its diastereomeric epoxide.

3.2. Synthesis of Epothilones A and C According to Danishefsky

In contrast to the afore described synthesis of epothilone A, Danishefsky et al. have chosen a quite different approach to construct the macrocyclic ring system (Fig. 8) [25, 26].

Synthesis of fragment C3-C11 (**23**) is accomplished in a multistep sequence starting from the known optically active aldehyde **22** while fragment C12-C2 (**25**) is synthesized in several steps starting from the commercially available (R)-glycidol **24**. The Suzuki-type coupling of the two fragments is achieved by the borane formed from **23** with the iodo olefine **25**.

As key intermediate for ring closure the enolate of acetate **26** is used in a stereoselective aldol reaction with the aldehyde. The cyclization proceeds smoothly since an enolization of the aldehyde is prevented by the adjacent quaternary center.

After deprotection a selective silylation of the 3- and 7-hydroxyl groups enables the oxidation of the 5-hydroxyl group to the ketone. The final deprotection leads to epothilone C which can be transformed into epothilone A as already described.

3.3. Synthesis of Epothilones B and D According to Nicolaou

In this first synthesis of epothilones B and D, a macrolactonization of **31** has been chosen as key step for the ring construction (Fig. 9) [27].

Fragment C7-C15 is produced via an unselective Wittig reaction of **28** with ketone **29**

Figure 7. Final synthesis of epothilones A and C

followed by selective desilylation and oxidation to the aldehyde **30**. Similar to the Schinzer approach, the C1-C6 fragment is introduced via a stereoselective aldol reaction. Macrolactonization under Yamaguchi conditions, chromatographic removal of the 12*E*-isomer and subsequent cleavage of the remaining protecting groups gives epothilone D, which is further oxidized to epothilone B.

3.4. Synthesis of Epothilone D According to Danishefsky

Another RCM approach to connect center C10 with C11 has been developed for the synthesis of epothilone D by Danishefsky et al. (Fig. 10) [28].

The required key compound **34** is prepared by a stereoselective aldol reaction between acetate **32** and ketoaldehyde **33**. After macrocyclization using the Grubbs-II catalyst the synthesis to epothilone D is accomplished by a reductive cleavage of the protecting group followed by a regioselective imine reduction of the less substituted double bond.

4. Occurrence and Biosynthesis

From the myxobacterial strain *Sorangium cellulosum*, epothilones are produced with yields of about 20 mg L^{-1}. The 16 hour doubling time makes a production in this organism economically less attractive. Therefore, this gene cluster

Figure 8. Synthesis of epothilones A and C according to DANISHEFSKY et al.

has recently been cloned and expressed in *Myxococcus xanthus*, a related host more amenable to genetic manipulation with a significantly shorter doubling time.

The biosynthetic pathway for the production of the epothilones in *S. cellulosum* has been elucidated and studied in detail [29 – 32]. The biosynthetic gene cluster (epo) has been isolated, sequenced, and found to code for six multifunctional proteins (Fig. 11). These proteins comprise nine polyketide (PKS) synthases (epoA, epoC - epoF) and one nonribosomal peptide (NRPS) synthetase (epoB). Finally, a P450 epoxidase converts epothilones C or D into the epoxide-bearing epothilones A or B, respectively.

In the meantime, mutant strains lacking the P450 epoxidase have been created to produce predominantly epothilones C and D in a 1:4 ratio. Further optimizations addressing culture medium, fermentation conditions and purification procedures led to a multigram synthesis of epothilone D [33 – 35].

5. Pharmacological Effects and Uses

The mitotic spindles that control the movement of chromosomes during cell division are composed of microtubules. Microtubules are formed from helical arrays of alternating α and β subunits of the protein tubulin. The formation of microtubules involves the assembly of tubulin

Figure 9. Synthesis of epothilones B and D according to NICOLAOU et al.

Figure 10. Synthesis of epothilones D according to DANISHEFSKY et al.

subunits bound to guanosine triphosphate, providing the energy for microtubule movement. Microtubules play a central role in cell structure, signaling, movement, and transport, as well as mitosis and meiosis. Disrupting these functions, therefore, leads to mitotic arrest followed by apoptosis.

Microtubules are recognized as clinically relevant targets for tumor therapy based on their integral role in cell division. Several naturally occurring cytotoxic agents disrupt cell division by affecting microtubule formation in a variety of ways. Vinca alkaloids prevent tubulin polymerization, while taxanes promote polymerization and disrupt microtubule dynamics. One of

the limitations of most taxanes and many other cytotoxic agents, however, is the development of resistance.

Approximately 75 % of cancers are either intrinsically unresponsive or develop resistance to treatment [36]. However, there is a new class of agents, the epothilones, which have a similar mechanism of action as Taxol® but exert an antiproliferative effect on cells that exhibit multidrug resistance. Unlike traditional drugs, such as colchicines, vincristine, or vinblastine, which stabilize tubulin but destabilize microtubules, taxanes and epothilones stabilize preformed microtubules. Both mechanisms have the potential to cause cell death; however, only epothilones possess the potential to overcome multidrug resistance in a variety of tumors [37, 38].

Similar to other tubulin-targeting small molecules, epothilones bind to the β subunit of heterodimeric tubulin, causing enhanced polymerization followed by hyperstabilization of the formed microtubules. Electron crystallographic structures of tubulin with epothilone A [39] or paclitaxel [40] have identified a common binding pocket for both compounds. Since the dynamic formation and dismantling of microtubules is necessary for cell division, epothilones induce G2/M mitotic arrest and apoptosis. Epothilones have shown broad potential as antitumor agents based on this unique mechanism of action [9].

Epothilones maintain potency against tumor cells with acquired resistance. Drug resistance is often associated with overexpression of the P-glycoprotein efflux pump, which actively removes drugs from affected cells. This process can be mimicked in the laboratory by exposing cells to increasing drug concentrations and selecting those that survive. Using this model, cells that are 45-times more resistant to paclitaxel than the parent cell line can be obtained in just 5 months [41]. Most epothilones possess the potential to exert an antiproliferative effect on cells that exhibit multidrug resistance, maintaining potency after in vitro selection processes that induce paclitaxel resistance.

Among the most prominent naturally occurring epothilones (types A-D), epothilone B shows the highest activity in vitro and in vivo. Epothilone B inhibits the growth of a large number of human cancer cell lines in vitro, representing most solid tumor types (Table 4). Growth inhibition also closely correlates with the induction of apoptosis, as indicated by the integrity of the plasma membrane. It appears that epothilone B is retained inside cells, leading to high intracellular concentrations that facilitate effective inhibition of tubulin polymerization.

Despite a promising profile in vitro, epothilone B is highly toxic in animal models in which different human cancer cell lines were xenografted to rodents. Furthermore, in human tumor cell lines that overexpress P glycoprotein, the addition of verapamil to block the efflux pump enhances the activity of epothilone B about 10-fold, indicating that epothilone B is still a substrate for P glycoprotein [42, 43]. Therefore, many attempts have been made to improve the properties of this natural compound with the goal to produce a more favorable therapeutic window. These efforts have resulted in three generations of epothilones under clinical development (Table 5).

First-generation epothilones are the compounds originally isolated from naturally occurring bacteria.

Second-generation epothilones are semisynthetic analogs of the natural products which have been modified to improve efficacy and tolerability.

Third-generation epothilones are fully synthetic and are designed to combine high efficacy, improved tolerability and lack of recognition by cellular resistance mechanisms in various solid tumors, including tumor types that are generally not sensitive to chemotherapy.

First results from clinical trials with some epothilones are promising indicating that epothilones have the potential to become a cornerstone in future cancer therapy.

1. Introduction

In the field of conventional, macroscopic process technology modeling and simulation approaches are by now used on a routine basis to design and optimize processes and equipment. Many of the models employed have been developed for and carefully adjusted to specific processes and reactors and allow flow and heat and mass transfer to be predicted, often with a high degree of accuracy. In comparison, modeling and simulation approaches for microreactors are more immature, but have great potential for even more reliable computer-based process engineering. In general, the purposes of computer simulations are manifold, such as feasibility studies, optimization of process equipment, failure modeling, and modeling of process data. For each of these tasks within the field of chemical engineering simulation methods have been applied successfully.

Microreactors (→ Microreactors) are developed for a variety of different purposes, specifically for applications which require high heat- and mass-transfer coefficients and well-defined flow patterns. The spectrum of applications includes gas and liquid flow as well as gas – liquid or liquid – liquid multiphase flow. The variety and complexity of flow phenomena clearly pose major challenges to the modeling approaches, especially when additional effects such as mass transfer and chemical kinetics must be taken into account. However, there is one aspect which makes the modeling of microreactors in some sense much simpler than that of macroscopic equipment: the laminarity of the flow. Typically, in macroscopic reactors the conditions are such that a turbulent flow pattern develops, which makes the use of turbulence models [1] necessary. With turbulence models the stochastic velocity fluctuations below the scale of grid resolution are accounted for in an effective manner, without the need to explicitly model the time evolution of these fine details of the flow field. Heat- and mass-transfer processes strongly depend on the turbulent velocity fluctuations, and for this reason the accuracy of the turbulence model is of paramount importance for a reliable prediction of reactor performance. However, currently (2006) there is no model available which is capable of describing turbulent flow phenomena in a universal manner and is computationally inexpensive at the same time. For this reason, simulation approaches for microreactors, which usually do not require turbulence models, offer some potential to make predictions with a degree of accuracy unparalleled by models of macroscopic reactors.

When comparing processes in microreactors with those in conventional systems, a few general differences can be identified:

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.k16_k01

- Flow in microstructures is usually laminar, in contrast to the turbulent flow patterns on the macroscale.
- The diffusion paths for heat and mass transfer are very short, and this makes microreactors ideal candidates for heat- or mass-transfer-limited reactions.
- The surface-to-volume ratio of microstructures is very high. Thus, surface effects are likely to dominate over volumetric effects.
- The fraction of solid wall material is typically much higher than in macroscopic equipment. Thus, solid heat-transfer plays an important role and must be accounted for when designing microreactors.

While the absence of turbulence simplifies many modeling tasks, the predominance of surface effects introduces additional complications, especially in the case of multiphase flow. Some of the fundamental mechanisms, for example, those of dynamic wetting and spreading phenomena, are not yet well understood, and this adds some degree of uncertainty to the modeling of these processes. As more and more practical applications of microfluidic systems emerge, research in the field of fluidic surface and interfacial phenomena gains additional impetus. It is thus hoped that in the following years refined models for microfluidic multiphase systems will be formulated and will add an additional degree of predictability to flow phenomena in microreactors.

When facing the task of formulating a model of a specific microfluidic system, the question arises whether the conventional macroscopic equations describing fluid flow and heat and mass transfer are still valid on the microscale. Systems for chemical processing rarely contain structures with dimensions smaller than 10 μm; the relevant length scale is often in the range of 100 μm. The standard approach to modeling transport processes in microreactors relies on a continuum description, i.e., continuum-field quantities such as pressure and velocity are introduced to represent the mean dynamics of the fluid molecules. The corresponding mathematical formulation is based on the Navier – Stokes equation and convection – diffusion equations for heat and mass transfer. The question to answer is whether or not this mathematical framework is suitable to describe transport processes in microreactors on the relevant length scales. Besides the continuum assumption there is one additional assumption on which the Navier – Stokes and related equations rest. This is related to the local statistical distribution of the particles in phase space: The standard convection – diffusion equations rely on the assumption of local thermal equilibrium. For gas flow, this means that a Maxwell – Boltzmann distribution is assumed for the velocity of the particles in the frame of reference co-moving with the fluid. When gas flow in microreactors at high temperature or low pressure is considered, this assumption may break down. The principle quantity determining the flow regime of gases and deviations from the standard continuum description is the Knudsen number Kn (Eq. 1).

$$\mathrm{Kn} = \frac{\lambda}{L} \tag{1}$$

The Knudsen number is the ratio of two length scales: the mean free path of the gas molecules λ and a characteristic length scale of the flow domain L, for example, the channel diameter. When Kn is larger than unity, a gas molecule is more likely to collide with the channel wall than with another molecule. As the transport of momentum or enthalpy is to a large extent governed by the collisions between molecules, major changes in the flow behavior are expected when the Knudsen number is on the order of unity. This may happen when gas flow through narrow channels is considered, but also when the temperature is high and/or the pressure is low.

Based on the Knudsen number, four different flow regimes can be distinguished [2]:

- Continuum flow with no-slip boundary conditions ($Kn \leq 10^{-2}$)
- Continuum flow with slip boundary conditions ($10^{-2} < Kn \leq 10^{-1}$)
- Transition flow ($10^{-1} < Kn \leq 10$)
- Free molecular flow ($Kn > 10$)

In the first two cases the Navier – Stokes equation can be applied, with modified boundary conditions in the second case. The computationally most difficult case is the transition flow regime, which, however, may be encountered in microreactor systems. Clearly, the defined ranges of Knudsen numbers are not rigid; they instead vary from case to case. However, the numbers given above are guidelines applicable to many situations encountered in practice.

For applications in the field of microreaction engineering, the conclusion can be drawn that the Navier – Stokes equation and other continuum models are valid in many cases, as Knudsen numbers greater than 10^{-1} are rarely obtained. This observation is supported by the fact that a typical mean free path of nitrogen at 1 bar is about 70 nm. However, it may be necessary to use slip boundary conditions to describe the flow in microchannels. The first theoretical investigations on slip flow of gases were carried out already in the 1800s by MAXWELL and VON SMOLUCHOWSKI. The basic concept relies on a so-called slip length L_s, which relates the local shear strain to the relative flow velocity at the wall (Eq. 2)

$$u_{\mathrm{gas}} - u_{\mathrm{wall}} = L_{\mathrm{s}} \frac{\partial u_{\mathrm{gas}}}{\partial y} \Big|_{\mathrm{Wall}} \tag{2}$$

where u_{gas}, u_{wall} refer to the gas and wall velocities parallel to the wall and y is the coordinate normal to the wall. The slip length L_s is depends on wall roughness and can be determined experimentally. Similarly, there is a relationship for the temperature jump across a solid surface in the slip-flow regime [2].

In the transition flow regime, which is rarely encountered in microreactors, the usual convection – diffusion equations cease to be valid. The general formulation to be applied in this regime is given by the Boltzmann equation, from which less involved model descriptions such as the Burnett equation can be derived via a low-*Kn* expansion [3]. However, rather than by a continuum model, transition flows are often computed based on the Direct Simulation Monte Carlo (DSMC) method [4]. Instead of modeling gas flow by a set of differential or integro-differential equations, this method is based on tracking the trajectories and interactions of gas molecules directly. DSMC is a time marching approach based on a time discretization with steps smaller than the collision time of the molecules. The computational demand for DSMC is much higher than for continuum approaches.

Similar to the case of gas flows, the question of the range of applicability of continuum models for liquid flow arises. While the kinetic theory of gases provides clear indications of the limits of continuum models and of the onset of rarefaction effects on the microscale, there is no general framework explaining possible deviations of liquid flow phenomena from their macroscopic behavior. The concept of mean free path ceases to be useful for liquids, as the molecules interact with their neighbors in a permanent manner (in a sense, the molecular mean free path is zero for liquids). Some groups have conducted experiments on liquid flows in microstructures and measured pressure drop and heat-transfer coefficients, with largely contradictory results [5 – 11]. A compilation of the published results does not seem to leave room for any simple conclusions of general importance. Furthermore, the physics of Newtonian liquids does not suggest any universal mechanisms by which the flow behavior in channels of several hundred micrometers in width could differ considerably from macroscopic behavior at the same Reynolds number. However, in some specific situations liquid microflows exhibit a behavior which does not occur on the macroscale, but which can be reproduced experimentally and explained by theoretical models.

Boundary slip of liquids is a first example of such effects. Since ca. 1995 it was confirmed that not only gases, but also liquids can exhibit boundary slip, with corresponding experiments indicating a slip length of a few tens of nanometers [12 – 14]. The phenomenon has also been studied by numerical simulations, especially the molecular dynamics (MD) method, which is based on solving Newton's equations of motion for an ensemble of mutually interacting molecules (see, e.g., [15]). MD simulation results confirm the existence of boundary slip for liquids and indicate how the slip length depends on molecular parameters and shear rate [16].

While slip-flow effects are mostly expected to have an impact on flow behavior on the submicrometer scale, there is another phenomenon which may lead to deviations from the usual model predictions on a larger length scale. On a solid surface exposed to an ionic liquid, charges may accumulate to form a Debye layer above the surface, to which an additional layer of immobilized charges is attached [17]. This so-called electric double layer (EDL) is related to accumulation of charges inside the liquid which act as sources of an electric field. In turn, this field is sensitive to changes in the EDL structure which may be induced by the flow in such a manner that inside a channel a field component in streamwise direction builds up. When ionic charges start to migrate in the electric field, liquid molecules

are dragged along with them and the apparent viscosity for channel flow changes. The phenomenon is known as electroviscous effect [18] and may cause a considerable modification of the friction factor in comparatively large channels. The electroviscous effect was studied theoretically for rectangular microchannels [19]. The channel width and height considered were in the range between 20 and 40 μm. Depending on the solute concentration, the friction factor was increased by up to 30 %, which shows that the electroviscous effect manifests itself on length scales much larger than the EDL thickness, typically on the order of a few nanometers. Thus, even in typical microchannel geometries ionic liquids may exhibit some "unexpected" behavior.

Many of the flow phenomena discussed here can be incorporated into continuum models such as the Navier – Stokes equation, an exception being gas flows in the transition and free molecular regimes. Only a modification of the boundary conditions and not of the model equations themselves is usually necessary, i.e., the nonstandard physics characteristic for the micro- and nanoscale mainly appears as a boundary effect. Thus, when attempting to model transport processes in microreactors, the continuum hypothesis is a far-reaching concept which covers most of the scenarios encountered in practice. For a more detailed discussion of the special aspects of micro- and nanoflows, see [20]. Along this line of arguments it becomes clear that to a large extent the problem of modeling transport phenomena in microreactors is a scaling problem: The familiar macroscopic model equations may be used, but they must be applied in an unfamiliar and possibly unexplored parameter range as far as the dimensionless groups characterizing the problem are concerned [21]. In that context, care must be taken to pay attention to effects which are usually neglected macroscopically, such as surface tension and viscous heating.

Most of the simulation techniques and results presented in the following chapters are based on a numerical solution of the macroscopic transport equations. As already mentioned above, owing to the laminar flow conditions, many of these studies can be regarded as first-principles calculations which are free of adjustable model parameters. Consequently, simulation results for microreactors are expected to have a high predictive power. The major limitation for the predictive power of the models is the large number of degrees of freedom, which often excludes the simulation of complete reactors and only allows focusing on components such as single channels. Thus, the true art of reactor modeling consists of selecting a suitable subsystem and representing the portions of the reactor neglected by appropriate boundary conditions. For many of the results reported in the following sections such a strategy was employed. When it is not clear how to select an appropriate subsystem or genuine system-level behavior to be studied, a macromodel approach may be chosen. One strategy of doing so is based on partitioning of the reactor domain into certain sections, each of which is characterized by a specific input – output behavior. As input to the model sections, thermodynamic forces such as pressure or temperature gradients are applied by which thermodynamic fluxes such as mass or heat flux are induced. An alternative strategy of macromodel generation is based on an averaging approach. By averaging over a large number of microscopic structures (e.g., channels) effective equations for volume-averaged field quantities can be derived, thus allowing the number of degrees of freedom for system-level modeling to be reduced considerably. In the following chapters, some examples for both of these modeling strategies which allow transport phenomena to be studied on the level of complete systems or at least larger subsystems will be given.

With continuum models being the basis for the simulation of microreactors, computational fluid dynamics (CFD) is the numerical method to be applied. By now, CFD techniques are routinely used in conventional chemical process engineering. In principle the very same methods can be employed for microreactors, with the possible drawback that the numerical algorithms have been optimized mainly for the parameter regime characteristic for macroscopic flows. The fundamentals of CFD are discussed in → Computational Fluid Dynamics; suitable introductions can be found in, e.g., [22].

2. Flow Distributions

Due to the specific microstructuring technology employed to build up microreactors, the geometric shape of the flow domain is often different from that in macroscopic equipment. While usually the elements for fluid transport such as pipes are of circular cross section, the channels in microreactors have a rectangular or trapezoidal cross section. Depending on the specific microstructuring technology, also tub-like grooves or close-to-triangular shapes may be obtained. Furthermore, a characteristic feature common to many microreactors is a comparatively wide flow distributor followed by a large number of parallel microchannels. In the following, the flow distributions in characteristic geometries and methods to obtain approximate flow distributions in highly parallel flow domains are discussed.

2.1. Straight Microchannels

For laminar flow in channels of rectangular cross section, the velocity profile can be determined analytically. For this purpose, incompressible flow is assumed. The flow profile can be expressed in form of a series expansion (see [23] and references therein) which, however, is not always useful for practical applications, where often only a fair approximation of the velocity field over the channel cross section is needed. An approximate solution of the form [24]

$$u(x,y)=u_{\max}\left[1-\left(\frac{x}{a}\right)^s\right]\left[1-\left(\frac{y}{b}\right)^r\right] \tag{3}$$

was suggested for a rectangular channel oriented along the z-axis with a width of $2a$ in the x-direction and a depth of $2b$ in the y-direction, where u is the local flow velocity and $u_{\max}$ the maximum velocity. The exponents s and r depend on the aspect ratio b/a of the channel. The most common correlations can be found in [23]. Typically, Equation 3 approximates the exact velocity profile with an accuracy of a few percent. Often, not the detailed velocity profile is of interest, but only the friction factor f, which determines the pressure drop over a channel of a given length. The fanning friction factor is defined as

$$f=-\frac{\mathrm{d}p}{\mathrm{d}z}\frac{D_\mathrm{h}}{2\rho U^2} \tag{4}$$

where $\mathrm{d}p/\mathrm{d}z$ is the pressure gradient along the channel, ρ the density, D_h the hydraulic diameter and U the mean flow velocity. The hydraulic diameter is given by $4A/P$, where A is the cross-sectional area of the channel and P its perimeter. A comparatively simple expression for the friction factor in rectangular channels [25] deviates from the analytical solution by less than 0.05 % (Eq. 4)

$$f=\frac{24}{\mathrm{Re}}\left(1-1.3553\alpha+1.9467\alpha^2-1.7012\alpha^3+0.9564\alpha^4-0.2537\alpha^5\right) \tag{5}$$

where α is the aspect ratio of the channel ($\alpha \leq 1$ by definition) and the length scale entering the Reynolds number Re is the hydraulic diameter.

Most expressions for the flow profile in rectangular channels assume that the flow is fully developed, i.e., that the flow velocity is oriented along the z-axis and does not change in streamwise direction. Close to the entrance of a channel this assumption is not valid, and the flow undergoes a development from an entrance distribution to a fully developed profile. Correspondingly, the pressure distribution deviates from that observed in a fully developed flow, and expressions for the friction factor such as Equation 5 are not valid in the entrance region. To determine the developing velocity distribution and friction factor, various approaches have been employed, such as analytical calculations based on a linearized inertia term, numerical solutions of the Navier – Stokes equation, and experimental velocity and pressure measurements. An overview of the results is given in [23]. In general, the pressure drop per unit length of an entrance flow is higher than that of a fully developed flow. To compare entrance flow effects, a hydrodynamic entrance length L_hy can be defined which is the length necessary to achieve a centerline velocity equal to 99 % of the fully developed value. Usually, a nondimensional quantity is used (Eq. 6).

$$L_\mathrm{hy}^+=\frac{L_\mathrm{hy}}{D_\mathrm{h}\mathrm{Re}} \tag{6}$$

Depending on the aspect ratio of the channel, values between 0.01 and 0.1 are found for the nondimensional entrance length [23]. From Equation 6 it can be deduced — given that L_hy^+ is Re-independent — that L_hy increases linearly

with the hydraulic diameter and the Reynolds number.

A number of authors have considered channel cross sections other than rectangular [25 – 27]. In general, an analytical solution of the Navier – Stokes and enthalpy equations in such channel geometries would be quite involved due to the implementation of the wall boundary condition. For this reason, usually numerical methods are employed to study laminar flow and heat transfer in channels with arbitrary cross-sectional geometry.

2.2. Periodic and Curved Channel Geometries

A key advantage of microreactors is their potential for rapid heat and mass transfer. Naturally, the acceleration of transport processes is related to the decrease of diffusion paths on the microscale. In addition, special channel geometries are explored for which a further speed up of heat and mass transfer is found. Three different channel shapes that have been studied are shown in Figure 1: zigzag sinusoidally curved, and converging-diverging. Velocity and temperature fields in zigzag channels were computed based on the finite-volume method for Reynolds numbers up to 1500 [28]. Above a specific Reynolds number depending on the geometry parameters, flow separation occurs, i.e., in the corners of the channel recirculation zones are formed. While the friction factor for straight channels displays a linear decrease as a function of Reynolds number, as is apparent from Equation 5, the friction factor in zigzag channels becomes nearly independent of the Reynolds number for $Re > 1000$. Data obtained for a zigzag channel with rounded corners show a similar trend [29].

Flow in sinusoidally curved channels for Reynolds numbers up to 500 was also studied with a finite-volume discretization [30]. For most of the parameter space explored, flow separation was not observed. However, for $Re = 500$ and a large enough sine-wave amplitude as compared to the period, there were some indications of recirculation zones forming in the recesses of the channel. Unfortunately, no attempt was made to compute friction factors.

Flow in converging-diverging channels was studied with special attention to the transition between laminar and turbulent flow [31] by using a spectral-element method in which the flow domain is divided into macroelements over which a set of polynomial test functions is defined. This method allowed damping of small-scale fluctuations due to numerical viscosity to be suppressed and is thus well suited to studying the transition from stationary to oscillatory and chaotic flow. The computed streamline patterns indicate a transition from unseparated flow at low Reynolds numbers to a flow with recirculation zones within the recesses of the channel, occurring at a comparatively small Reynolds number between 10 and 20. Streamline patterns for various Reynolds numbers are depicted in Figure 2. The phenomenology of flow distributions in such channel domains was found to be quite diverse. At low Reynolds numbers the flow is stationary, but at a Reynolds number of 150 oscillations begin to develop, with the vortices still being confined in the recesses. At Re = 400 the viscous forces are no longer strong enough to confine the vortices in the recesses and vortex ejection is observed. At even higher Reynolds numbers the flow becomes aperiodic and chaotic.

In some cases, for example, when long residence times are desired, comparatively long microchannels must be integrated into a compact micro reaction device, a task which can only be achieved with curved channels. In addition, straight channels are often not suited for connecting a microflow domain to the external world. One of the first theoretical studies on flow in curved channels [32, 33] investigated the secondary flow perpendicular to the main flow direction induced by inertial forces by means of a perturbative analysis. The dimensionless group characterizing such transverse flows is the Dean number.

$$K = \mathrm{Re}\sqrt{\frac{D_\mathrm{h}}{R}} \tag{7}$$

where D_h is the hydraulic diameter and R the mean radius of curvature of the channel. The typical secondary flow pattern in curved channels is given by two counterrotating vortices separated by the plane of curvature. The strength of these vortices increases with increasing Dean number.

Originally, the studies of secondary flow in curved channels were performed for pipes of circular cross section. Of much greater relevance to

Figure 1. Different channel shapes for which flow distributions have been computed: zigzag (upper left), sinusoidally curved (upper right), and converging-diverging (bottom)

Figure 2. Streamline patterns in a converging-diverging channel for various Reynolds numbers, taken from [31]

microreactors are rectangular channels, which were the subject of detailed numerical investigations [34] into the formation of vortices in channels of square cross section, for which a complex branch structure was found describing the transition between flow patterns with two and four counterrotating vortices. Up to a Dean number of about 113, a two-vortex solution is found, followed by a transition regime between Dean numbers of 113 and 130 with coexisting two- and four-vortex configurations. For $K > 130$ the flow exhibits a four-vortex pattern which, however, coexists with a two-vortex pattern of broken symmetry. The friction factor in curved channels was found to be larger than in straight channels for most of the Dean number range considered, and not surprisingly different branches of the flow map are associated with different friction values.

2.3. Multichannel Flow Domains

In chemical microprocess technology it is important to guarantee well-defined and repro-

ducible reaction conditions in microchannels, but a high throughput should also be achieved. For this purpose, the process fluid is guided through a large number of parallel microchannels, where heat exchange and/or chemical reactions occur. One of the characteristic problems of microprocess technology is to equally distribute the incoming fluid over the microchannels. Fluid maldistribution would induce unequal residence times in different channels, with undesired consequences for the product distribution of a chemical reaction being conducted inside the reactor. When a process with various competing side reactions and byproducts is considered, the contact time of the process fluid in the reaction region should be as well defined as possible to maximize the selectivity of the process. However, not only the maldistribution of the fluid over a multitude of microchannels induces variations of the contact time, but also hydrodynamic dispersion of concentration tracers in the channels themselves.

Various concepts for the equipartition of fluid over a multitude of microchannels have been developed. One concept relies on guiding the incoming fluid through a flow splitter with subsequent bifurcations [35]. The most widely used design is based on a comparatively wide inlet region leading into a multitude of narrow microchannels. A corresponding geometry, developed for methanol reforming, is shown in Figure 3. The figure shows the computational domain of the CFD model of the reactor together with the computed streamlines, where use of reflection symmetry was made and only one quarter of the portion of the reactor to be considered was modeled. An inlet pipe leads to a flow distribution chamber connected with a multitude of microchannels. The essence of such designs is to be seen in the pressure barrier of the microchannels. The narrower the microchannels are, the higher will be the pressure drop in the channels themselves as compared to the pressure drop in the flow distribution chamber, and the more uniform the flow distribution will be.

During the development of the microreformer of Figure 3 one of the goals was to design the flow manifold in such a way that the volume flows in the different reaction channels are approximately the same [36]. In spite of the recirculation zones found, for the chosen design a flow variation of about 2 % between different channels was predicted from CFD simulations. In the application under study, a washcoat catalyst layer is applied to the microchannels. Thickness variations of the catalyst layer are likely to play the leading role in the nonuniformities in flow distribution to be expected. Hence, a flow manifold with intrinsic volume flow variations of a few percent over different reaction channels is usually satisfactory.

For the computation of the flow distribution in the methanol-reforming reactor, a reduced-order flow model for the microchannels was used. In such a model a fully developed flow profile as given by Equation 3 is assumed, which means that entrance flow effects are neglected. This approximation is justified when the entrance length is small compared to the total length of the channel. A major advantage of a reduced-order flow model is the significant reduction of the degrees of freedom entering the simulation. Each microchannel is then only represented by a single degree of freedom, that is, the total volume flow, and resolution of the corresponding flow domain by a computational grid is no longer required. Thus the simulation of microfluidic devices comprising a large number of channels becomes possible at moderate computational cost.

Finite-volume grids in combination with reduced-order flow models for microchannels allow flow distribution problems to be solved in 3D, for which the standard approach would be computationally too expensive. However, when the goal is to find designs with optimum flow equipartition by tuning specific geometric parameters, it is advisable to set up models with significantly fewer degrees of freedom. The flow distribution in multichannel microreactors was studied with the help of macromodels [37]. The geometry considered was a microstructured plate of a heat-exchanger stack developed at the Institute of Microtechnology Mainz. The plate together with arrows indicating the flow direction is shown on the left side of Figure 4; on the right side the model is displayed together with the geometric parameters. The model is based on the idea of subdividing the flow domain into a number of virtual channel segments with rectangular cross section over which the flow is distributed. Through the channel segments in the inlet zone the volume flows $V_1, V_2, \ldots, V_{\mathrm{Nc}}$ are transported, where a part of the flow branches off into the actual microchannels of width W_{c}

Figure 3. Streamlines in the flow distribution chamber of a multichannel reactor

and depth e. For each of the channel segments a relationship between the pressure drop Δp and the average flow velocity u of the form

$$\Delta p = 32\lambda_{\mathrm{Nc}} \frac{\mu L u}{D_{\mathrm{h}}^2} \tag{8}$$

was used, where the hydraulic diameter is defined as

$$D_{\mathrm{h}} = \frac{2we}{w+e} \tag{9}$$

In these expressions, μ is the dynamic viscosity, L the length of the channel segment, w and e are its width and depth, and λ_{Nc} is a correction factor accounting for the noncircularity of the channels. Clearly, the above formulas rely on the assumption of a hydrodynamically developed flow.

By means of the model depicted in Figure 4, Equation 8, and Equation 9 it is possible to compute the flow distribution just by solving a comparatively low-dimensional system of linear algebraic equations. The problem resembles the task of computing the current distribution of an electric circuit. A priori it is not clear whether the approximation to subdivide the flow domain in the described way is justified. To assess the quality of the chosen approximation, the flow field was computed by means of the finite-volume method [37]. The results obtained suggest that, owing to the orientation of the isobars of the flow and the absence of recirculation loops, the chosen subdivision into channel segments is a reasonable simplification, at least for the geometry and flow regime considered. The model allows the flow distribution to be studied for a variety of different geometries with a minimum computational effort. As a result of simulations, optimized flow chamber geometries leading to a maximum of flow equipartition were determined.

While the strategy described above is a way to obtain effective, low-dimensional models for multichannel reactors in various cases, it clearly has its limitations. In geometries with hundreds of microchannels, another method can be utilized to compute the flow field. In a situation where the flow is distributed over a large number of parallel microchannels, the multitude of channels can be regarded as a porous medium. For porous media effective, volume-averaged transport equations have been known for a long time (for an overview, see [38]). To solve a flow distribution problem for a multichannel geometry, the flow domain can be split into several regions, one of which is the flow distribution chamber, and another the region comprising the multitude of channels. In the flow distribution chamber, the ordinary transport equations are solved, whereas in the multichannel domain, the effective, volume-averaged description of the transport processes is used. A corresponding 2D geometry is shown in Figure 5. The incoming flow is distributed over a large number of channels of width of w_{c} separated by walls with a width of $w - w_{\mathrm{c}}$.

The most straightforward porous-medium model which can be used to describe the flow in the multichannel domain is the Darcy equation [38], which represents a simple model used to relate the pressure drop and the flow velocity inside a porous medium. Applied to the geometry of Figure 5 it is written as

$$\frac{\mathrm{d}}{\mathrm{d}y} \langle p \rangle_{\mathrm{f}} + \varepsilon \frac{\mu}{K} \langle u \rangle_{\mathrm{f}} = 0 \tag{10}$$

with the porosity ε and permeability K given as

$$\varepsilon = \frac{w_{\mathrm{c}}}{w}, \quad K = \frac{\varepsilon\, w_{\mathrm{c}}^2}{12} \tag{11}$$

The flow velocity, pressure and dynamic viscosity are respectively denoted as u, p, and μ and

Figure 4. Geometry of the microstructured plates (left) and subdivision of the flow domain into channel segments (right), as considered in [37]

Figure 5. Multichannel geometry with channels and separating walls of uniform width

the symbol $<\ldots>_{\mathrm{f}}$ represents an average over the fluid phase. [39]. An extended Darcy equation was used to model the flow distribution in a microchannel cooling device. In general, the permeability K must be regarded as a tensor quantity accounting for the anisotropy of the medium. Furthermore, the description can be generalized to include heat-transfer effects in porous media.

Compared to the use of reduced-order flow models, the porous-medium approach allows an even larger multitude of microchannels to be dealt with. Furthermore, for comparatively simple geometries with only a limited number of channels, it represents a simple way to provide qualitative estimates of the flow distribution. However, as a course-grained description it does not reach the same level of accuracy as reduced-order models. Compared to the macromodel approach [37], the porous-medium approach has a broader scope of applicability and can also be applied when recirculation zones appear in the flow distribution chamber. However, the macromodel approach is computationally less expensive and can ideally be used for optimization studies.

3. Heat Transfer

Heat-transfer phenomena belong to the key issues to be studied in microreactors. Due to the small thermal diffusion paths, microreactors have the potential to enable fast heat transfer and to control temperature distributions with very high accuracy. Correspondingly, modeling and simulation of heat-transfer phenomena and their reliable prediction is of paramount importance for process design. The simulation of temperature distributions in microreactors often requires the solution of a conjugate heat transfer problem, i.e., the temperature fields in the fluid phase and in the solid wall material must be computed. Owing to the microstructuring technologies used to fabricate microreactors, the share of wall material in the total reactor volume is often higher than in conventional equipment. Hence, solid heat conduction effects become important and usually have to be taken into account when the temperature field inside a reactor is to be computed.

3.1. Straight Microchannels

A standard geometry of channels in microfluidic systems is a rectangular or close-to-rectangular cross section. With a given velocity profile, the temperature field inside rectangular channels can often be determined analytically. However, the problem of determining a temperature profile in a channel geometry is much more multifaceted than the computation of a flow distribution. While in most cases a zero-velocity boundary condition at the channel walls is prescribed for the flow, the wall-boundary conditions for the temperature field can be diverse. On the one hand, either a heat flux or a temperature can be prescribed. On the other hand, the thermal boundary conditions on the four walls of a rectangular channel may be different. Due to this complexity, the solution for temperature field itself is usually not reported. Rather, the Nusselt number, defined as

$$\mathrm{Nu}=\frac{\alpha D_{\mathrm{h}}}{k} \tag{12}$$

is determined. In this expression, D_{h} is the hydraulic diameter, k the thermal conductivity of the fluid, and α the heat-transfer coefficient measuring the transmitted thermal power per unit area divided by a characteristic temperature difference. The Nusselt number is a dimensionless quantity characterizing the efficiency of heat transfer. Similar to the velocity field, the temperature field assumes an invariant profile far enough downstream from the channel entrance. However, due to the continuous heat transfer from or to the channel walls, only the shape of the temperature distribution stays invariant, but the normalization changes. Close to the entrance of the channel a thermally developing flow may be observed. A thermal entrance flow is not a priori related to a hydrodynamic entrance flow, i.e., a thermally developing flow may be observed even in regions where the flow is hydrodynamically developed and vice versa.

An overview of the Nusselt numbers obtained for rectangular channels with various aspect ratios and various thermal boundary conditions has been given [23]. Depending on the thermal boundary conditions, the Nusselt number for thermally fully developed flow either increases or decreases when the aspect ratio is increased. When the Nusselt number for thermally developing and hydrodynamically developed flow is plotted as a function of position along the channel, a divergence is observed when the channel entrance is approached. This means that, with decreasing distance to the channel entrance, increasing heat transfer efficiency is found. The same observation is made when a simultaneously (i.e. hydrodynamically and thermally) developing flow is considered. Analogously to hydrodynamically developing flows, a thermal entrance length L_{th} can be defined. It is given as the duct length required for the Nusselt number to fall within a 5 % interval of the fully developed value. Again, a dimensionless quantity

$$L_{\mathrm{th}}^{+}=\frac{L_{\mathrm{th}}}{D_{\mathrm{h}}\mathrm{Re}\,\mathrm{Pr}} \tag{13}$$

is used, where the Prandtl number Pr is the ratio of the momentum diffusivity (i.e. the kinematic viscosity) and the thermal diffusivity. The dimensionless thermal entrance length is a quantity only depending on the aspect ratio of the channel and the thermal boundary conditions. Hence, L_{th} is a linear function of the hydraulic diameter, the Reynolds number, and the Prandtl number.

Apart from rectangular channels, heat transfer has also been studied in channels with different cross-sectional geometries, and Nusselt

numbers for wall boundary conditions of fixed temperature and fixed heat flux are tabulated for different geometric parameters [25, 26].

3.2. Periodic and Curved Channel Geometries

Similar to the computation of friction factors, heat transfer has not only been studied in straight channels, but also in channels with specific periodic shapes. Nusselt numbers in the zigzag channels shown in Figure 1 were computed by using a finite-volume approach in two dimensions [28]. With increasing Reynolds number the Nusselt number increases significantly as compared to a straight channel, i.e., a parallel-plate arrangement. For suitable geometric parameters, a Reynolds number in the range of 1000 and a Prandtl number of 8, a heat-transfer enhancement factor of about 13 was computed. For a Prandtl number of 0.7 (corresponding to air) the ratio of the heat fluxes achieved with the zigzag and the straight channels at identical values of pumping power and pressure drop were compared. The zigzag channel outperforms the straight channel by up to a factor of 6, i.e., for the same pumping power or pressure drop a considerably higher heat flux is achieved. This is an interesting result in view of the design of micro heat exchangers, in which the goal is often to increase the heat flux while limiting the pressure drop.

A zigzag geometry with rounded corners was studied in 2D by the finite-volume method [40]. The Prandtl number was kept fixed at 0.7 and the Reynolds number was varied between 100 and 1000. For the range of geometric parameters considered, a heat-transfer enhancement factor of about 3 was found at $Re = 1000$, and this confirms the potential of corrugated channels for heat-transfer enhancement.

Heat transfer in sinusoidally curved channels was studied for a Prandtl number of 1.0. [30] Surprisingly, at a Reynolds number of 100 the Nusselt number is lower than the corresponding value in a parallel-plate channel. Such a suppression of heat transfer stands in contradiction to results for sine-wave channel walls of comparatively large amplitude [41], for which heat-transfer enhancement increased with increasing Reynolds number, with an enhancement factor of about 4 for $Re = 800$. Both of these studies were restricted to steady-state flows, and steady-state solutions could be determined for the range of Reynolds numbers considered. Experimental work on flow and heat transfer in sinusoidally curved channels [42] indicate heat-transfer enhancement and do not show evidence of decreasing Nusselt number in any range of Reynolds numbers. However, the flow patterns begin to exhibit some unsteady behavior for Reynolds numbers greater than about 200 in the geometry considered. Interestingly, oscillations were predominantly observed close to the exit of the channel and were found to move upstream when the Reynolds number was increased. Much of the heat-transfer enhancement was attributed to the unsteady character of the flow [42].

The flow and temperature field in an elementary cell of the converging-diverging channel geometry for which flow fields were calculated in [31] was computed on the basis of the finite-volume method using periodic boundary conditions [43]. As far as the transition between a steady-state and an unsteady flow is concerned, similar results were found. At Reynolds numbers beyond the transition to the unsteady flow regime, the temperature field evaluated for a Prandtl number of 0.7 becomes quite complex. This is indicated in Figure 6, which shows the evolution of (normalized) temperature contour lines at a Reynolds number of 328. To quantify heat-transfer enhancement, the time-averaged Nusselt number was computed. The increase in Nusselt number compared to a straight channel was found to be significant and reached values as high as 7.54 at a Reynolds number of 520. Flow and heat transfer in converging-diverging channels were analyzed based on a perturbation analysis derived from lubrication theory and on the finite-volume method [44]. Most of these studies were limited to Reynolds numbers up to 100. In this regime the increase in Nusselt number compared to a parallel-plate geometry was moderate, amounting to a factor of about 1.3 at $Re = 100$ and $Pr = 1$. The results also showed an approximately linear increase of heat-transfer enhancement as a function of Prandtl number. The studies of [45] indicated that heat-transfer enhancement in converging-diverging channels is significantly reduced if the separation between the wavy channel walls is bigger than the wavelength of the undulations. Here a cubic

Figure 6. Evolution of the temperature field in the recesses of a converging-diverging channel, as obtained in [43]

spline collocation method was used to numerically solve the transport equations and, in contrast to the other studies, a cyclic structure of the flow and dimensionless temperature fields with the period of the wall structures was not assumed. The results obtained at $Re = 500$ and $Pr = 6.93$ show a rather moderate heat-transfer enhancement factor of about 1.8 compared to a parallel-plate geometry, which is further reduced for smaller Prandtl numbers.

Similar to the structure of the flow field, heat transfer has also been studied in curved channel geometries. The complicated branch structure with competing patterns of two and four counterrotating vortices in channels of square cross section is reflected in the Nusselt number [34]. When plotting the Nusselt number as a function of Dean number, different branches are found corresponding to symmetric and asymmetric secondary flow patterns with two and four vortices. However, the relative difference between the different branches is not very pronounced and should be hard to measure experimentally. For a Dean number of 210 and a Prandtl number of 0.7 a heat-transfer enhancement factor of about 2.8 was determined, that is, curved channels as well as other channels with specific periodically varying cross sections may be used for applications where rapid heat transfer is desired.

3.3. Multichannel Flow Domains

When a large number of parallel microchannels is considered, the problem of computing the temperature distribution inside the channels and the channel walls becomes quite involved. In such a case the use of the method of reduced-order flow models discussed in Section 2.3 is not as straightforward as in the case of a pure flow distribution problem, due to thermal cross-talk between the different channels. In principle, heat transfer in a multichannel domain can be described on the basis of a porous-medium model, in which an average is taken over an ensemble of channels and continuous field quantities are introduced. However, in the standard models for porous media, a thermal equilibrium between the fluid and the solid phase is assumed, i.e., only a single temperature field is used. Especially in the regime of large Péclet numbers the thermal-equilibrium assumption may break down, and it

may become necessary to define separate temperature fields for the fluid and the solid phase. It is thus advisable to take one step back and to derive the mean-field model equations that allow heat transfer in multichannel domains to be described on the basis of a volume-averaging approach.

A generic geometry of a multichannel stack to which the mean-field equations should be applied is shown in Figure 7. Many microchannels, usually several hundred up to several thousand, are arranged in layers stacked onto each other. As a whole the multichannel stack forms a cuboid of extension L_x, L_y, L_z in x-, y-, and z-direction, respectively. The microchannels of width w_f and depth h_f are assumed to be parallel to the z-axis and are separated by solid walls of thickness w_s and height h_s, respectively.

The need for modeling single channels and their specific geometry is eliminated when regarding the reaction fluid and wall material as interpenetrating continua. Hence, in the following it is assumed that the reactor stack is filled with interpenetrating fluid and solid phases which interact via the exchange of heat. Momentum exchange between the two phases is not accounted for explicitly and it is assumed that the velocity distribution over the cross section of the reactor is known a priori. The phase volume fractions can be derived from the geometric parameters h_f, h_s, w_f, and w_s and are given as

$$\Phi_\mathrm{f}=\frac{w_\mathrm{f}h_\mathrm{f}}{(w_\mathrm{f}+w_\mathrm{s})\,(h_\mathrm{f}+h_\mathrm{s})},\quad \Phi_\mathrm{s}=1-\Phi_\mathrm{f} \tag{14}$$

The temperature field of the solid phase can change due to heat conduction or due to heat transfer from the fluid phase. For the fluid, heat conduction does not have to be taken into account since the flow domain consists of disconnected channels, but convective heat transfer due to the flow velocity as well as heat transfer from the solid is included. In the xy plane no conduction within the fluid without intermediate transfer to the solid walls can occur. The reason for not including heat conduction in the z-direction is the fact that in most cases of practical relevance it is negligible when compared to convective transport. Following the derivation of [46], the fluid and solid temperature fields T_f and T_s are obtained as solutions of the equations

$$\begin{aligned}\rho_\mathrm{f}c_\mathrm{f}\left(\frac{\partial}{\partial t}+u_i\frac{\partial}{\partial x_i}\right)T_\mathrm{f}&=-\alpha a_\mathrm{V}\,(T_\mathrm{f}-T_\mathrm{s})+S_\mathrm{c}\\ \rho_\mathrm{s}c_\mathrm{s}\frac{\partial}{\partial t}T_\mathrm{s}&=k_{ij}\frac{\partial}{\partial x_i}\frac{\partial}{\partial x_j}T_\mathrm{s}-\alpha a_\mathrm{V}\,(T_\mathrm{s}-T_\mathrm{f})\end{aligned} \tag{15}$$

where c_f, c_s are the fluid and solid specific heats, u_i is the average velocity of the fluid (averaged over a channel cross section), α the heat transfer coefficient from the channel walls to the fluid, a_V the specific surface area (wall surface/reactor volume), and the Einstein convention of summation over repeated indices has been used. This convention will be used throughout this chapter when vector or tensor quantities are involved. The fluid and solid densities are volume-averaged quantities and given as

$$\rho_\mathrm{f}=\Phi_\mathrm{f}\rho_\mathrm{f}^{(0)},\quad \rho_\mathrm{s}=\Phi_\mathrm{s}\rho_\mathrm{s}^{(0)}, \tag{16}$$

where the superscript (0) indicates the corresponding material densities. The equation for the fluid temperature contains a source term S_c which could, e.g., represent the input of thermal energy from a chemical reaction. Owing to the anisotropy of the solid matrix the thermal conductivity is direction-dependent. For this reason a thermal conductivity tensor k_ij appears in Equation 15. The heat-transfer coefficient α can be obtained from well-known correlations for rectangular channels. The model of Equation 15 can be regarded as a mean-field model expected to describe the average temperatures of the fluid and the solid phase without incorporating the local fluctuations which are due to temperature gradients within single channels or channel walls.

To compute the thermal conductivity tensor k_ij, the multitude of walls shown in Figure 7 can be regarded as a network of thermal resistors. On this basis, the components of the thermal conductivity tensor are derived as

$$\begin{aligned}k_{xx}&\approx(w_\mathrm{f}+w_\mathrm{s})\left(\frac{h_\mathrm{f}+h_\mathrm{s}}{h_\mathrm{s}}w_\mathrm{f}+w_\mathrm{s}\right)^{-1}k_\mathrm{s}\\ k_{yy}&\approx(h_\mathrm{f}+h_\mathrm{s})\left(\frac{w_\mathrm{f}+w_\mathrm{s}}{w_\mathrm{s}}h_\mathrm{f}+h_\mathrm{s}\right)^{-1}k_\mathrm{s}\\ k_{zz}&\approx\Phi_\mathrm{s}k_\mathrm{s}\end{aligned} \tag{17}$$

where k_s represents the thermal conductivity of the solid material. All other components of the thermal conductivity tensor vanish.

The mean-field model described here was developed to compute temperature fields in microreactors with low computational effort. Previously, a 2D version of such a model was used to determine the temperature distribution in a microchannel heat sink [39]. To assess the quality of the 3D mean-field model, the resulting

Figure 7. Multichannel stack comprising a large number of parallel microchannels

temperature fields were compared with results from a full conjugate heat-transfer model explicitly accounting for all of the geometrical details of the multichannel stack. The results of such a comparison are displayed in Figure 8. The temperatures were evaluated along the centerline of the reactor pointing in the z-direction. The heated region with nonzero source term extends up to 1 mm downstream from the inlet plane. The temperature curves show that in the inlet region the fluid and solid temperatures are not equilibrated, and this underlines the necessity of a two-temperature model. The same conclusion was drawn on the basis of the 2D model [39]. Overall, a good agreement between the mean-field and the full model is found, with maximum local differences in temperature of 2 – 3 K and a total temperature range of about 35 K.

The times needed to numerically solve the equations of the two models were found to differ by orders of magnitude. This makes the mean-field description an especially promising method for fast evaluation of reactor designs. When developing a micro reaction system it is often unclear how exactly the properties of the channel walls (geometry, thermal conductivity) influence the reaction performance. Usually, the goal is to achieve a temperature distribution as uniform as possible, in order to suppress unwanted side reactions and to increase the selectivity of the process. Based on the volume-averaging approach presented here it should be easy to assess and compare the thermal performance of different reactors and to identify favorable designs.

3.4. Micro Heat Exchangers

Micro heat exchangers are used for rapid heat transfer between a hot and a cold fluid; owing to the small thermal diffusion paths, the size of the system can be reduced compared to conventional devices. Among the different flow schemes (cocurrent, countercurrent, and cross-current) especially the countercurrent scheme has been studied theoretically, because of the practical relevance of countercurrent heat exchangers on the one hand, and the fairly simple model structure compared to cross-current heat exchangers on the other. A schematic drawing of a countercurrent micro heat exchanger is shown in Figure 9. A characteristic feature of such devices is the fact that the thickness of the wall material separating the channels is of the same order of magnitude as the channel depth itself. This distinguishes micro heat exchangers from their macroscopic counterparts, in which the width of the flow passage is usually well above the wall thickness.

Owing to the comparatively large share of wall material, longitudinal heat conduction in the channel walls must be taken into account when attempting to formulate a heat-exchanger model. In contrast, the models for conventional

Figure 8. Fluid (left) and solid (right) temperatures in a multichannel stack as obtained from the full (dots) and the mean-field model (lines)

heat exchangers usually account only for transverse heat transfer from one fluid to another.

The performance of countercurrent micro heat exchangers was investigated, especially with respect to wall conduction effects and the choice of wall material [47], for a flow of nitrogen in channels with a length of 10 mm, a depth of 50 μm, and separating walls with a thickness between 125 and 500 μm. To reduce the computational effort, the heat exchanger geometry was only discretized in the axial direction, i.e., in the direction of the flow. In the direction perpendicular to the flow a fixed heat-transfer coefficient was used to describe the exchange of heat between the fluid and the channel walls.

When the thermal conductivity of the wall material is varied, characteristic temperature profiles for the channels with the hot and cold fluids and the channel wall are obtained. For very small values of the thermal conductivity, no heat is exchanged and the temperatures stay approximately constant. At intermediate wall thermal conductivities, almost linear temperature profiles are obtained, while at very high thermal conductivities the wall assumes a constant temperature and the temperatures of the fluids change rapidly in the entrance regions of

Figure 9. Schematic drawing of a countercurrent micro heat exchanger

the channels. A quantity characterizing the performance of a heat exchanger is the efficiency, which is the ratio of the transmitted heat and the maximum transmittable heat, given as

$$\varepsilon = \frac{T_{\text{in}}^{\text{hot}} - T_{out}^{hot}}{T_{\text{in}}^{\text{hot}} - T_{\text{in}}^{\text{cold}}} \tag{18}$$

in the case of equal volume flows of two identical incompressible fluids; T_{in} and T_{out} denote the temperatures at the channel in- and outlet, respectively. The heat-exchanger efficiency was calculated for a couple of characteristic geometries as a function of the wall thermal conductivity [47]. A typical result for equal volume flows is displayed in Figure 10. At low conductivities almost no heat is transferred, as expected. At high conductivities the wall assumes a uniform temperature due to axial heat conduction and the device becomes indistinguishable from a cocurrent heat exchanger, which is limited to an efficiency of 50 % at equal volume flows. At values around 1 W m^{-1} K^{-1} the curve assumes a maximum, as axial heat conduction inside the walls is suppressed to a sufficient degree and transverse conduction to the neighboring channels is still efficient. Hence, in typical micro heat exchangers the use of low-conductivity materials such as glass or polymers is preferable, and the common stainless steel materials are expected to reduce the efficiency.

Figure 10. Heat-exchanger efficiency as a function of the thermal conductivity of the wall, taken from [47]

Heat losses to the exterior by conduction through the walls belong to the aspects not considered in the analysis in [47]. The vertical edges of the rectangular walls shown in Figure 9 are in thermal contact with the housing or the flow distribution manifold of the heat exchanger, and by these means heat is transferred to the surroundings. This effect was studied [48] by using a similar pseudo-1D model as [47], discretized only in the flow direction. Equal mass flow rates and identical incompressible fluids were assumed. The results were expressed as functions of the two independent dimensionless parameters of the problem, the conduction parameter

$$\lambda = \frac{kA}{\dot{m}\, c_p L} \tag{19}$$

and the number of transfer units

$$\text{NTU} = \frac{\alpha A}{\dot{m}\, c_p} \tag{20}$$

where k is the thermal conductivity of the wall material, A the cross-sectional area of a wall, $\dot{m}$ the mass flow, c_p the specific heat of the fluid, L the channel length, and α the heat-transfer coefficient between the fluid and the wall. As a result of the computational model, the heat-exchanger efficiency (or effectiveness) and the ratio of the conduction to the flow losses was obtained (Fig. 11). The conduction losses represent the heat flux dissipated to the surroundings via conduction through the walls, while the flow losses account for the fact that the cold fluid is not heated to the inlet temperature of the hot fluid (the thermodynamic limit) and vice versa. Figure 11 shows that the conduction losses are usually larger than the flow losses. Especially for a highly conductive wall material they exceed the flow losses by one order of magnitude or more. Thus, in combination with the results of Figure 10 the need for a low-thermal-conductivity construction material for countercurrent micro heat exchangers is underpinned in a most distinct way.

Figure 11. Effectiveness and ratio of conduction to flow loss as a function of NTU and conduction parameter for a countercurrent micro heat exchanger, taken from [48]

The studies of [47, 48] are both based on a description which assumes a vanishing transverse heat-transfer resistance within the channel walls, i.e., temperature gradients within the walls pointing in streamwise direction. A more elaborate model allowing for computation of the complete 2D temperature field in the wall material based on a Fourier expansion [49] confirmed that, with the exception of the close vicinity of the channel inlets and within the parameter range studied, transverse gradients are negligible, and thus corroborates the usefulness of pseudo-1D models for micro heat exchangers.

4. Mass Transfer and Mixing

Similar to heat transfer, fast mass transfer is one of the key aspects of microreactors. Again, due to the short diffusion paths, microreactors enable rapid mass transfer and a uniform solute concentration within the flow domain. Good control of reactant concentration throughout the whole reactor volume is a prerequisite for highly selective chemical reactions and helps to avoid hazardous operation regimes. In addition, overcoming mass-transfer limitations by rapid mixing allows the rapid intrinsic kinetics of chemical reactions to be exploited and enables higher yield and conversion. However, when dealing with liquid-phase reactions, fast mixing remains a challenge even at length scales of 100 µm or less due to the small diffusion constants in liquids.

Micromixing has been a very active field of research [50 – 52]. Not all of the micromixers reported in the literature are suitable candidates for microprocess engineering. On the one hand, the Reynolds numbers in microreactors are usually higher than those in Lab-on-a-chip devices which are often of the order of unity. On the other hand, microreactor processes are typically continuous flow processes for which batch-type micromixers are of little value. Owing to these differentiations, this section will mainly concentrate on mixing concepts and designs suitable for microprocess engineering and will highlight some specific simulation methods for micromixers.

4.1. Simple Mixing Channels

The simplest micromixer is the so-called mixing tee (Fig. 12, left). Two inlet channels merge into a common mixing channel where mixing of the two co-flowing fluid streams occurs. The mixing characteristics of T-type mixers were investigated by using CFD methods [53]. Mixing of gases in a channel of 500 µm width was considered and certain geometric parameters such

Figure 12. Schematic design of a mixing tee (left) and CFD results for mixing of gases in a channel of 500 µm width and 300 µm depth (right), taken from [53]

as the aspect ratio of the mixing channel or the angle at which the two inlet channels meet were varied. To quantify mixing, a mixing length was defined as the length in flow direction after which the gas composition over all positions of a channel cross section deviates by no more than 1 % of the equilibrium composition. The CFD results for the mixing length as a function of Péclet number $Pe = \bar{u}\ d_{\mathrm{h}}/D$ are displayed on the right side of Figure 12, where $\bar{u}$, d_{h}, D are the average flow velocity, hydraulic channel diameter, and molecular diffusivity, respectively. The maximum Reynolds number considered was about 17.

In addition to the CFD results, estimates of the mixing length based on the Fourier number

$$\mathrm{Fo} = \frac{Dt}{l^2} \tag{21}$$

are shown in the figure. The Fourier number relates a residence time t in the mixing channel to the molecular diffusion constant D and a characteristic length scale l, which is the width of the channel. For a given value of Fo and a given flow rate the length along the mixing channel necessary to achieve the corresponding Fourier number was determined. As is apparent from Figure 12, the Fourier number is a reasonable indicator for mixing, which occurs for Fourier numbers between 0.1 and 1.0. Consequently, l^2/D is an order-of-magnitude representation of the mixing timescale. The linear increase of the CFD-based

mixing length as a function of Péclet number points to a very simple mixing mechanism by diffusion between co-flowing fluid lamellae. Obviously, complex convection-dominated mixing mechanisms (e.g. driven by swirls or recirculating flows) are absent in the simple mixing-tee configuration for the range of Reynolds numbers studied.

When the Reynolds number is increased, a regime with a flow pattern of broken symmetry is reached [54]. At a Reynolds number of about 140 the symmetric flow pattern becomes unstable and an engulfment flow with an increased area of material interface between the two fluids is found. This is illustrated in Figure 13, which shows maps of the computed concentration field over cross sections of the mixing channel for Reynolds numbers ranging from 119 (a) to 239 (f). The increase in material interface is related to an increase in mixing efficiency, and thus a mixing tee is more efficient than predicted by simple models accounting for mass transfer through an interface located in the symmetry plane of the mixer.

In cases where symmetry breaking and the corresponding engulfment flows are absent (i.e. at sufficiently small Reynolds numbers) the steady-state concentration field in a mixing tee can be computed based on an analytical approach. The underlying assumption is that the flow moves with uniform velocity. Ref. [51] gives the following Fourier series expansion for the concentration field in a mixing channel of width w with two streams of equal viscosity and a volume flow ratio of $r/(1-r)$

$$\frac{c(x,y)}{c_0} = r + \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{\sin nr\pi}{n}\cos\frac{n\pi y}{w} \exp\left(-\frac{2n^2\pi^2}{Pe+\sqrt{Pe^2+4n^2\pi^2}}\frac{x}{w}\right) \quad (22)$$

where the concentrations in the two streams at the channel entrance are $c = c_0$ and $c = 0$ and Pe is the Péclet number based on the channel width. The coordinates in length and in width direction of the microchannel are denoted as x and y, respectively. With such an analytical expression the evaluation of mixing performance in a simple microchannel is very time efficient. However, an even simpler analysis based on the Fourier number already gives the correct order of magnitude for the mixing length, as indicated in Figure 12.

4.2. Chaotic Micromixers

The performance of mixing tees is usually not sufficient for liquid-mixing applications, since corresponding diffusion constants are of the order of 10^{-9} m^2/s or smaller, and mixing times far below one second may be required. As described above, mixing in straight channels occurs mainly by diffusion between co-flowing streams with a characteristic time constant of l^2/D. A reduction of the mixing timescale can be achieved if diffusion is superposed by convective transport. On the macroscale, convective transport is often due to turbulent eddies, and only in the very final stages of the mixing process does diffusion play a role. Unfortunately, in microscopic geometries flow is usually laminar, and a different convection mechanism must be devised to speed up mixing.

Much attention has been devoted to creating flow schemes in micromixers which enhance the mixing performance by convective transport. In that context it was found that chaotic flows bear a great potential for speeding up mixing. The corresponding principle of chaotic advection has been studied for quite some time [55], but it has only more recently been implemented in microchannel flows. Chaotic advection is synonymous with complex flow patterns in which extreme stretching and backfolding of fluid volumes occurs. It is very difficult to numerically study chaotic micromixing of liquids. The reason lies in the discretization artifacts from which most CFD schemes suffer, specifically the phenomenon of numerical diffusion [56, 57]. Owing to discretization errors artificial fluxes are induced which, for specific differencing schemes, take the form of diffusive fluxes and thus artificially increase the diffusion constant. The magnitude of numerical diffusion depends on the cell-based Péclet number (evaluated with the extension of a grid cell as length scale) and the relative orientation of the grid cells and the flow velocity. Specifically, if the flow is parallel to the grid lines, the diffusivity perpendicular to the flow direction is zero. In the case of a simple, regular flow pattern it is often possible to align the computational grid with the velocity field and thereby suppress numerical diffusion without having to prohibitively increase grid resolution. However, in the case of a chaotic flow

Figure 13. Concentration field over the channel cross section of a mixing tee for Reynolds numbers of 119 (a), 139 (b), 146 (c), 159 (d), 186 (e), and 239 (f), reproduced from [53]

this is no longer possible and numerical diffusion often severely falsifies the computational results.

To evaluate the performance of chaotic micromixers, the standard CFD methods for solving convection – diffusion equations must be abandoned and replaced by a method which is largely free of discretization artifacts. Such a method is Lagrangian particle tracking, which is based on tracking the paths of massless particles in a given flow field. Assuming that the flow velocity u_i is given, the particle trajectories are obtained as solution of the equation

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = u_i \tag{23}$$

where x_i denotes the position vector of a particle. The mixing process is then studied by seeding the inlet of the mixer with a multitude of particles and recording how these particles have been redistributed by the flow at a downstream position. The fact that Equation 23 does not contain any contribution of Brownian particle motion is often not a real drawback. If the flow itself displays a large degree of chaoticity, much of the redistribution of the initial concentration field is done solely by convective transport, and diffusion only completes the mixing process. In a coarse-grained description in which concentrations are evaluated by computing the particle numbers in specific grid cells, the inclusion of Brownian motion would not modify the results significantly in many cases.

The computational effort for Lagrangian particle tracking can be reduced if the mixing section exhibits some periodicity. The structures inducing the chaotic flow are often arranged in a certain spatial period for which the flow field may be computed using periodic boundary conditions. Particles are then seeded onto the entrance plane of this section of the mixing channel and tracked up to its exit plane. The fluid streamlines map each point of a channel cross section (x_k, y_k) to another point (x_{k+1}, y_{k+1}) of the corresponding cross section after one period of the fluidic structures, as shown in Figure 14.

Such a so-called Poincaré map can be written formally as

$$(x_{k+1}, y_{k+1}) = P\left[(x_k, y_k)\right]. \tag{24}$$

The function P can be computed either from an analytical or a numerical representation of the flow field, making use of Equation 23. In such a way, a 3D convection problem is essentially reduced to a mapping between two-dimensional Poincaré sections. The complete mixing process can be analyzed by successive application of the Poincaré map.

Figure 14. Section of a mixing channel with a map P connecting the points of two cross-sectional planes

Lagrangian particle tracking techniques have been used to evaluate the performance of several chaotic micromixers. One of the first micromixers for which convincing evidence for chaotic mixing was given is based on a design known as staggered herringbone mixer (SHM) [58]. The corresponding mixer geometry is shown in Figure 15. The bottom of the channel of height h and width w contains a staggered arrangement of grooves, whereby a fraction p of the bottom channel wall has grooves inducing a helical flow with a left-handed recirculation, and the remaining bottom wall fraction induces a right-handed recirculation. Schematic views of the channel cross section including projections of the streamlines are shown at the top of Figure 15. If $p \neq 1/2$, the vortex pattern is asymmetric, and a superposition of two patterns exhibiting the larger of the two vortices on the left and on the right side, respectively, could result in chaotic flow. In a generalized sense, this is an implementation of the "blinking-vortex principle" [59]: two vortex structures can be superposed in an alternating fashion to create a chaotic flow pattern. In the SHM the superposition is achieved by the alternating, staggered groove patterns shown in Figure 15. The lower part of the figure shows channel cross sections with two streams of fluorescent and clear solutions after 0, 0.5, and 1 cycle. The images were recorded using a confocal microscope. The two different vortices are clearly visible, and the third frame shows first indications of a chaotic disturbance of the flow.

Mixing in the SHM has been analyzed using Lagrangian particle tracking [60]. By comparison with a mixer containing only simple groove structures (as opposed to staggered herringbone structures) evidence was given for the superior performance of chaotic micromixers. The Poincaré sections obtained from particle tracking were compared to the confocal micrographs of Figure 15 [58]. The computed particle distributions (Figure 16) show strong similarities to the distributions of fluorescence intensity, and thus prove that mixing in complex flows can realistically be described by Lagrangian particle tracking. With standard CFD techniques resting on the solution of a convection – diffusion equation for the concentration field this is often not possible, since discretization errors would have blurred the thin lamellae visible in Figure 16.

Lagrangian particle tracking has also been applied to analyze chaotic mixing in a number of other channel designs. Simulation Studies [61] on a twisted microchannel [62] showed that for Reynolds numbers above 10 mixing is mostly chaotic, apart from a few unmixed, regular islands. Cross-channel micromixers have been studied by a number of authors [63 – 65]. In such devices multiple side channels intersect with the main mixing channel. An oscillating pressure is imposed on the side channels such that the time-averaged flow rate entering the main channel is zero. The flow entering from the side channels distorts the material interface of the two fluids to be mixed, thereby increasing the interfacial area and promoting mixing. The analysis of mass transfer based on Lagrangian particle tracking has shown that, for suitable values of the pressure excitation amplitude and frequency, chaotic mixing is induced [63].

Many of the studies on micromixing reported in this section are more or less geared towards Lab-on-a-chip applications, i.e., the target Reynolds number is about 10 or smaller. In microreactors throughput is often a more impor-

Figure 15. Micromixer geometry with staggered groove structures on the bottom wall, as considered in [58] (reprinted with permission, © 2002, AAAS). The top of the figure shows a schematic view of the channel cross section with the vortices induced by the grooves. At the bottom, confocal micrographs show the distribution of two liquids over the cross section. Flow is from left to right.

Figure 16. Comparison of confocal micrographs [58] (left) with the Poincaré sections obtained from Lagrangian particle tracking [60] (right).

tant issue than in Lab chips and, correspondingly, Reynolds numbers are higher and may easily reach values of several hundreds. A quite simple micromixer which is well suited for this Reynolds number regime was analyzed theoretically and experimentally [66]. The design of the mixer is shown at the bottom of Figure 17. The mixing channel consists of a number of arclike segments of alternating curvature, two of which are shown in the figure. As discussed in Section 2.2, a helical flow develops in such curved channels, with vortices appearing in the projection of the velocity field onto the channel cross section. For Dean numbers larger than 140 the flow exhibits four counterrotating vortices, as indicated by the CFD results shown in the middle of Fig-

Figure 17. Two segments of a meandering mixing channel [66] (bottom) and CFD results showing the projected velocity fields on different cross-sectional planes (middle). The upper part of the figure shows the positions of massless particles initially seeded along the material interface after six channel segments.

ure 17. In the mixer proposed by [66] a chaotic flow is created by alternating between the flow patterns in different channel segments, with the smaller pair of vortices either appearing in the right or the left half of the cross-sectional plane.

To study the mixing performance, a modified version of the usual Lagrangian particle tracking was developed. Usually, two types of tracer particles are distributed over the entire entrance plane and the mixing quality is computed by counting the number of particles in grid cells on a plane located at a downstream position. Based on this method it is difficult to obtain reliable results for states close to complete mixing. In an alternative method [66] only the material interface is seeded with particles (indicated as the

dotted line in the upper half of one channel cross section in Fig. 17) and the length of the intersection of this interface with cross-sectional planes at various downstream positions is computed. This length scale should provide a good measure for mixing, since all the mass transfer proceeds through the material interface, and can be computed with high accuracy, since the same number of particles usually distributed over a plane can now be distributed along a line.

The upper part of Figure 17 shows the distribution of particles along the material interface after six channel segments for a Dean number of 200. The particles are distributed over almost the entire cross-sectional plane and thus document the pronounced and very complex stretching and folding of the interface. For Dean numbers above 100 an exponential growth of interfacial length scale as a function of residence time in the channel could clearly be proven. From these results it is apparent that mixing proceeds in a chaotic manner. This statement was underpinned by experimental results which showed that the position of close-to-complete mixing along the channel is virtually independent of the flow rate.

4.3. Multilamination Micromixers

The chaotic micromixers described in Section 4.1 offer a quite elegant solution to the micromixing problem, as complicated manifolds for distributing the fluid streams are no longer required and mixing is achieved by the intrinsic structure of the flow field. However, if the flow is chaotic in one part of the channel domain and regular in the other, unmixed islands, which usually deteriorate process performance, will remain. Thus, before using a chaotic micromixer in practice its mixing performance should be carefully evaluated over the whole range of Reynolds numbers considered. In comparison, multilamination mixers often require much more complex distribution manifolds and channel structures, but their mixing performance can usually be better controlled and predicted over the operation range envisioned.

The principle of mixing by multilamination relies on the creation of a multitude of thin fluid lamellae between which mixing occurs by diffusion. Thus, the mixing times achievable with multilamination mixers are directly related to the diffusion timescales between neighboring fluid lamellae. Figure 18 exemplifies the basic flow structure in a multilamination mixer: A multitude of fluid streams is guided through a flow chamber of varying width. For the mixer in the figure the streams are focused into a narrow channel by which the characteristic diffusion path is drastically reduced and mixing is enhanced.

Figure 18. Multilamination mixer focusing a multitude of fluid streams through an inlet chamber into a narrow mixing channel. Alternating fluid inlets are distributed over a circular arc-shaped manifold.

In a similar way as in Section 4.1 an analytical formula can be derived which allows for a fast computation of the concentration field in a multilamination mixer. By transforming the spatial coordinate in streamwise direction (x in Eq. 22) into a time coordinate by dividing the spatial differerential by the average flow velocity and integrating from the inlet to the outlet of the mixer, a 2D spatial problem is reformulated as a problem with one space and one time coordinate. Thus, in a frame of reference co-moving with the flow and assuming a plug-flow profile, the convection – diffusion problem is transformed into a pure diffusion problem. The resulting diffusion equation can be solved by the usual Fourier-transform techniques. A corresponding analytical model for multilamination mixing has been developed [67] which takes into account changes of the channel width along the flow path, i.e., it incorporates effects of focusing or defocusing, with the former often being used to speed up mixing. Specifically, a coordinate s orthogonal to the fluid lamellae is introduced which may be a curvilinear coordinate in regions where focusing or defocusing occurs. It is assumed that s

lies between $-w/2$ and $w/2$, where w is a measure for the channel width. The concentration field is then expanded in harmonics

$$\frac{c(s,t)}{c_0} = \frac{1}{2} + \sum_{n=0}^{\infty} a_n(t) \sin\frac{k_n s}{w}, \quad k_n = (2n+1)\pi \tag{25}$$

where only the sine terms contribute if the total number of fluid lamellae is even and initial concentrations of c_0 and 0 are considered. The time dependence of the concentration field arises from the fact that a frame of reference co-moving with the flow is chosen, as described above. Inserting this expansion into the diffusion equation in the co-moving frame of reference allows $a_n(t)$ to be determined as

$$a_n(t) = a_n(0) \exp\left(-Dk_n^2 \int_0^t \frac{\mathrm{d}t'}{w^2(t')}\right), \tag{26}$$

where D is the molecular diffusivity. The function $w(t)$ incorporates the changes in channel width. In contrast to a channel of constant width an integral must be evaluated to determine the Fourier coefficients. This integral represents the history of the mixing process and accounts for the changes in mixing speed due to width variations.

Clearly, the model of Equations 25 and 26 should also be applicable to a simple mixing channel with only two fluid streams as considered in Section 4.1, i.e., Equation 22 should be recovered when transforming to a formulation with two spatial coordinates instead of a space – time description. However, the difference between the two formulations is that Equation 22 also takes into account diffusion in streamwise direction, an effect that becomes important at small Péclet numbers. Nevertheless the model for multilamination mixing is useful in most practical cases, since diffusion in streamwise direction is usually negligible. This model is free of numerical diffusion and thus not only allows faster, but also more reliable prediction of mixing performance in specific cases. The fast evaluation of mixing performance allows parameter studies to conducted which would have been extremely time consuming when using standard CFD techniques [68].

Reducing the solution of the convection – diffusion equation for the concentration field to a 1D problem in the co-moving frame-of-reference clearly reaches its limits if the fluid lamellae become deformed and are no longer arranged in parallel. Such a situation may occur if the channel depth is not small compared to its width and the design comprises a sudden expansion or contraction of the flow passage. Multilamination mixers with cornerflow geometries have been analyzed by CFD techniques, and situations where the multilamination pattern suffers strong deformations identified [69]. The complex flow patterns found in such mixers may also mislead experimentalists who attempt to evaluate the mixing performance by photometric techniques based on the diffusion of a solute [69].

Creating a multitude of lamellae such as in Figure 18 usually requires a quite complex flow distribution manifold. There is, however, an alternative multilamination principle which enables multiplication of the number of lamellae along the mixing channel: split-and-recombine (SAR) mixing. An SAR mixer consists of successive mixing elements each of which causes a doubling of the number of lamellae. An example of such a mixing element is shown in Figure 19. The flow entering the element in positive z-direction is split into two substreams which are then recombined. Thereby the number of fluid lamellae is increased from two to four. For n successive mixing elements, the number of lamellae is increased to 2^{n+1} and the diffusion paths are reduced correspondingly. The exponential reduction of diffusion paths resembles mass transfer in chaotic flows, where fluid volumes are stretched and folded such that the width of fluid filaments decreases exponentially. For this reason SAR mixers are usually very efficient, without the need for incorporating very small channels. Furthermore, in contrast to some chaotic mixers SAR mixers guarantee a largely uniform mixing quality over the entire channel cross section.

For the channel design shown in Figure 19 it could be shown that lamellae multiplication works in a close-to-ideal manner for Reynolds numbers below about 30 [70]. For higher Reynolds numbers inertial forces become important and cause deformation and finally merging of lamellae of the same type. Altogether, experiments indicate that at comparatively small Reynolds numbers the design shown enables an efficient liquid mixing at low pressure drops, and thus the SAR mixer is especially qual-

Figure 19. Mixing element of an SAR mixer (left) and optical micrographs showing lamellae multiplication in the first three mixing elements (right)

ified for the processing of highly viscous liquids [70].

As far as the computation of concentration fields in SAR mixers is concerned, the challenges are greater than in ordinary multilamination mixers. The reason is that the number of lamellae does not remain constant; rather, there are discontinuous transitions between patterns with n and $2n$ lamellae. A strategy to deal with this problem has been formulated [67]: based on solving a 1D diffusion equation in a co-moving frame-of-reference (Eqs. 25 and 26), the mixing element shown in Figure 19 is subdivided in two sections. In the first section, the flow passes through two separate branches, and in the second section it only passes through one branch. In each of these sections the time evolution of the Fourier coefficients is computed by Equation 26. At the interface, the downstream Fourier coefficients are obtained from a sum involving the upstream Fourier coefficients. In addition, the evolution of the concentration field in a complete SAR mixer comprising several successive mixing elements is obtained in an iterative manner from the analysis of a single mixing element, i.e., the Fourier coefficients on the outlet plane shown in Figure 19 are identified with the coefficients on the inlet plane of the next element. Thus the degree of mixing was computed as a function of position along the channel, and reasonable agreement with experimental data was found [67]. Thus, the usefulness of the 1D model for multilamination mixing is corroborated by experimental data, and reasonable results can be obtained even for such complex situations involving flow passages of varying width as well as flow splitting and recombination.

There are alternative flow topologies for SAR mixers which have been proven to cause a multiplication of fluid lamellae. The design of mixing element shown in Figure 19 was especially optimized with regard to extending the Reynolds number range in which the SAR principle is implemented, consistent with the throughput requirements typical for microreactors. The disadvantage is that this mixing element poses major challenges for microfabrication. When only very small Reynolds numbers must be considered the design constraints are less severe, and a design which is easier to fabricate has been proposed [71]. The flow topology is such that a doubling of the number of fluid lamellae is achieved after two SAR steps, and the functionality with respect to lamellae multiplication has been proven by using dyed aqueous solutions. In the same spirit as above, the model of Equation 25 and 26 can be used to compute the evolution of concentration fields in such a mixer if the upstream and downstream Fourier coefficients at the branching points are matched with each other.

4.4. Hydrodynamic Dispersion

Mass transfer of a solute dissolved in a fluid is not only the fundamental mechanism of mixing processes, it also determines the residence-time

distribution in microfluidic systems. As mentioned in Section 2.3, in many applications it is desirable to have a narrow residence-time distribution of concentration tracers being transported through a microfluidic system. An initially narrow concentration of tracer will suffer broadening (i.e., dispersion) due to two different effects. First, in some regions of the flow domain of a system the fluid velocity will be smaller than in others, and this leads to a longer residence time of molecules being transported preferably through these parts of the domain. However, due to Brownian motion the molecules will also sample some of the other regions with higher flow velocity. Hence, molecular diffusion may reduce the dispersion of a concentration tracer. On the other hand, by diffusion an initially localized concentration tracer in a fluid at rest will be dispersed. From these arguments it becomes clear that hydrodynamic dispersion depends on a quite subtle interplay of convective and diffusive mass transfer, and the evolution of a concentration tracer as it is transported through the flow domain depends on various factors such as the flow profile, the magnitudes of the flow velocity, and the diffusion constant.

The key analysis of hydrodynamic dispersion of a solute flowing through a tube [72, 73] assumed a Poiseuille flow profile in a tube of circular cross section and showed that for large enough times the dispersion of a solute is governed by a one-dimensional convection – diffusion equation

$$\frac{\partial \bar{c}}{\partial t}+\bar{u}\,\frac{\partial \bar{c}}{\partial x}=D_e\frac{\partial^2 \bar{c}}{\partial x^2} \tag{27}$$

where $\bar{c}$ is the concentration averaged over the cross section of the tube, $\bar{u}$ the average velocity, and D_e an effective diffusivity, also denoted dispersion coefficient, which is given by

$$D_e=D+\frac{\bar{u}^2R^2}{48D} \tag{28}$$

where D is the molecular diffusivity, and R the radius of the tube. The factor 1/48 multiplying the velocity-dependent term is generic for tubes of circular cross section and is modified when other geometries are considered. In many cases the second term, which can be rewritten as $DPe^2/48$, dominates over the first, which is a purely diffusive contribution. Hence, due to convection a concentration tracer is usually dispersed much more strongly than it would have been by diffusion alone. A notable feature of Equation 27 and 28 is their independence of any initial condition. Independent of how the solute is distributed over the channel cross section and along the channel initially, the Taylor – Aris [72, 73] description is valid in the limit of long times ($t\cdot\cdot$). When exactly this limit is reached with a given accuracy depends on the initialization of the concentration field. A rough guideline is provided by the Fourier number of Equation 21, evaluated with the tube radius as length scale. The Fourier number can be regarded as a dimensionless time coordinate which compares the actual time to the time a molecule needs to sample the cross-sectional area of the tube. The validity of the description should be related to the condition that the Fourier number assumes values on the order of 1 or larger.

The above analysis was extended to arbitrary time values for the dispersion of an initially plug-like profile [74], i.e.

$$c\,(x,r,0)=\{\begin{matrix} c_0\ (|x|\leq l/2) \\ 0\ (|x|>l/2)\end{matrix} \tag{29}$$

where r is the radial coordinate of the tubular geometry, and l the length of the plug. A generalized evolution equation was derived for the area-averaged concentration of the form

$$\frac{\partial\,\bar{c}}{\partial t}=\sum_{n=1}^{\infty}k_n\,(t)\,\frac{\partial^n\,\bar{c}}{\partial x^n} \tag{30}$$

which is valid without any restriction on t. The derivatives in the infinite series appearing on the right-hand side are multiplied by time-dependent dispersion coefficients k_n. In the Taylor – Aris limit, all of the dispersion coefficients except k_1, which describes the convection of the tracer with the flow, and k_2, which determines the spreading of the tracer, are negligible. When moving to smaller times, the time-dependence of k_2 needs to be taken into account, while all higher dispersion coefficients are still negligible [74]. Only at very small times do the higher dispersion coefficients become important. For the case considered, k_2 can be regarded as time-independent for Fourier numbers greater than about 0.5 [74].

Even if the results discussed above highlight some of the most important aspects of hydrodynamic dispersion, they were based on cylindrical ducts, which are not the generic geometry

used in the field of microfluidics. In chemical microprocess technology, tubular sections are used to connect different units, but the channels contained in microreactors typically have a rectangular or tublike cross section. Dispersion in rectangular channels was studied in detail [75]. The evolution equation (Eq. 27) is still valid in this case, but the expression for the dispersion coefficient (Eq. 28) needs to be modified. While a simple analytical expression for the dispersion coefficient related to flow between parallel plates could still be obtained [76], the corresponding expression for rectangular channels is a complicated series expansion. This is not surprising, since the exact form of the flow profile in a rectangular channel is given in form of an infinite series as well. A simpler relationship approximates the exact expression for the dispersion coefficient in rectangular channels within an error of 10 % [77]. In addition, the tub-like channel cross sections which are typically obtained by isotropic etching processes were considered by employing a numerical scheme that allowed computation of the dispersion coefficient. On this basis, different channel geometries were compared, and favorable and less favorable designs identified.

In cases where hydrodynamic dispersion and the corresponding broadening of residence-time distributions deteriorate the performance of a process, the question arises which channel design minimizes dispersion. Already from the Taylor – Aris analysis it becomes clear that enhanced mass transfer perpendicular to the main flow direction reduces the broadening of concentration tracers. Such a mass transfer enhancement can be achieved by the secondary flow occurring in a curved channel. This aspect was investigated for ducts of circular cross section [78] under the assumption that the diameter of the duct is small compared to the radius of curvature, and the convection – diffusion equation for the concentration field was solved numerically. More specifically, a two-dimensional problem defined on the cross-sectional plane of the duct was solved based on a combination of a Fourier series expansion and an expansion in Chebyshev polynomials. The solution is of the general form

$$D_e^{cur} = D\left[1 + Pe^2 f(K, Sc)\right], \tag{31}$$

where D_e^{cur} is the dispersion coefficient in curved ducts, D the molecular diffusivity, Pe the Péclet number of the flow, and the function f depends on the Dean number K defined in Equation 7 and on the Schmidt number Sc, which is the ratio of the kinematic viscosity and the diffusivity. The following asymptotic behavior for the ratio of the dispersion coefficients in curved and straight ducts was found [78]:

$$\frac{D_e^{cur}}{D_e}\begin{cases} = 1 & K \to 0 \\ \propto K^{-1} & K \to \infty \end{cases}. \tag{32}$$

In curved channels secondary flow patterns of two or four counterrotating vortices are formed. These vortices redistribute fluid volumes in a plane perpendicular to the main flow direction. Such a transverse mass transfer reduces dispersion, a fact reflected in the K^{-1} dependence in Equation 32 at large Dean numbers. For small Dean numbers, the secondary flow is negligible, and the dispersion in curved ducts equals the Taylor – Aris dispersion of straight ducts.

Similar to the case of mixing, the transverse redistribution of matter in a curved channel can be improved in a sequence of channel segments of alternating curvature. By superposition of different vortex patterns a chaotic flow is induced [66]. By Lagrangian particle tracking in combination with a CFD computation of the flow field it can be shown that the residence-time distribution of tracers in the channel built from segments as shown in Figure 17 becomes very narrow and approaches a deltalike distribution of zero width. In practice, however, the width of the residence-time distribution is limited by the molecular diffusivity of the tracers, which was neglected in the simulations [66]. Nevertheless, a substantial reduction of hydrodynamic dispersion can be achieved in a meandering channel when compared to a straight channel.

5. Chemical Kinetics

Most plants or reactors in chemical microprocess technology inevitably contain a unit in which chemical conversion takes place. The goal might be to produce a fine chemical with a high yield and selectivity or to screen a large number of reactions in parallel. Hence, a thorough understanding of chemical kinetics is a key requirement for the successful design and optimization of micro reaction devices. For this purpose, reliable models of reaction kinetics cou-

pled to the transport equations of momentum, heat, and matter are needed.

The type of kinetic model to be used depends on the type of reaction considered. For a homogeneous reaction occurring in the bulk of the fluid, a power-law kinetic model is often appropriate (see, e.g., [79]). In such models the rate of a certain reaction depends on a product of powers of the species concentration. On the other hand, heterogeneously catalyzed reactions are often conducted in microreactors. In a strict sense, power-law kinetics do not capture the dynamics of such processes over the full range of pressure, temperature, and concentrations. Instead, a more complicated kinetic model of, e.g., the Langmuir – Hinshelwood type [80] would have to be used. Nevertheless, power-law kinetics is frequently applied to heterogeneously catalyzed processes in a limited parameter range to simplify the description.

Independent of the specific modeling strategy, the kinetic equations often exhibit a nonlinear dependence on the species concentrations and a reaction rate rapidly increasing with temperature. In combination with the transport equations for mass, momentum, and heat, the resulting numerical problem is usually challenging due to the nonlinearities and the multitude of timescales involved. For this reason, methods are needed to eliminate some of these difficulties and to simplify the numerical structure.

5.1. Numerical Methods for Reacting Flows

The solution of the species concentration equations in combination with the momentum and the enthalpy equation generally requires an iterative procedure. A rough sketch of the numerical structure of a stationary reacting-flow problem is given as

$$\begin{bmatrix} A_{cc} & A_{cu} & A_{cT} \\ A_{uc} & A_{uu} & A_{uT} \\ A_{Tc} & A_{Tu} & A_{TT} \end{bmatrix} \begin{bmatrix} c \\ u \\ T \end{bmatrix} = \begin{bmatrix} b_c \\ b_u \\ b_T \end{bmatrix}, \tag{33}$$

where c, u, and T denote the vectors of concentration, velocity, and temperature fields, respectively. Owing to the nonlinear nature of the problem, the coefficients of the different matrices $A_{\alpha\beta}$ still depend on the unknowns c, u, and T. The cross-coupling between different field quantities is provided by those matrices $A_{\alpha\beta}$ with $\alpha \neq \beta$. The set of nonlinear algebraic equations is solved iteratively, i.e., starting with an initial guess the approximation is successively improved until convergence is reached. Depending on the nature of the chemical reaction term entering the species-concentration equation, different strategies may be applied to solve Equation 33. For intrinsic kinetics characterized by a much shorter timescale than transport of momentum, heat, and matter, it is often preferable to set up an iteration scheme in which a number of iterations of the species-concentration equation are performed during one iteration cycle of the remaining equations. However, for a fast reaction which is limited by heat and mass transfer (e.g. in a situation where the reactants are not premixed), comparable iteration cycles of the species-concentration equation and the remaining equations might be sufficient.

Apart from the coupling of chemical kinetics to the transport equations, the chemical reaction dynamics themselves may pose numerical challenges when a number of different reactions are superposed. In such a case the rate of disappearance of a chemical species i can be written as

$$-\frac{\dot{n}_i}{V} = R_{ij} r_j, \tag{34}$$

where r_j is the rate of the jth reaction, and R_{ij} a matrix defining how a specific reaction contributes to a change in concentration of the chemical species involved. For brevity the Einstein convention of summation over repeated indices was used. Quite frequently it occurs that the timescales characterizing the different reactions vary by orders of magnitude, such that the fast reactions are already completed while the slow reactions have not yet progressed to any appreciable degree. The corresponding stiff differential equations are usually solved by an implicit time-integration scheme which allows comparatively large time steps without suffering from numerical instabilities or predicting unrealistic asymptotic states [81]. However, implicit time integrators involve the solution of a (generally nonlinear) algebraic system of equations for each time step, which is done by some iterative scheme such as Newton's method. For reaction systems with a broad spectrum of timescales these iteration schemes can fail to converge, with the consequence that very small time steps must be

chosen. Such a situation is related to high computational costs, and methods are needed to simulate extremely stiff reaction systems more efficiently.

Methods based on the partitioning of a reaction system into fast and slow components were proposed [82 – 84]. A key assumption made in this context is the separation of the space of concentration variables into two orthogonal subspaces Q_s and Q_f spanned by the slow and fast reactions. With this assumption the time variation of the species concentrations is given as

$$-\frac{\dot{n}_i}{V}=(Q_{s,j})_i\left(\dot{y}_s\right)_j+(Q_{f,j})_i\left(\dot{y}_f\right)_j. \tag{35}$$

The notation is such that $(Q_{\mathrm{s},j})_i$, $(Q_{\mathrm{f},j})_i$ denote the ith component of the jth basis vector in the subspace of slow and fast reactions, respectively. The corresponding expansion coefficients are $\left(\dot{y}_s\right)_j$ and $\left(\dot{y}_f\right)_j$, respectively, and are expressed by the reaction rates via

$$\left(\dot{y}_s\right)_i=\left(Q^T_{s,j}\right)_i R_{jk}r_k, \tag{36}$$

$$\left(\dot{y}_f\right)_i=\left(Q^T_{f,j}\right)_i R_{jk}r_k. \tag{37}$$

If the timescale of the fast reactions is much shorter than that of the slow reactions, it can be assumed that the former are completed at an initial stage of the latter. Mathematically, this assumption reads

$$\left(Q^T_{f,j}\right)_i R_{jk}r_k=0. \tag{38}$$

Equation 38 represents a set of algebraic constraints for the vector of species concentrations expressing the fact that the fast reactions are in equilibrium. The introduction of constraints reduces the number of degrees of freedom of the problem, which now exclusively lie in the subspace of slow reactions. In this a way the fast degrees of freedom have been eliminated, and the problem is now much better suited for numerical solution methods. It has been shown that, depending on the specific problem to be solved, the use of simplified kinetic models allows the computational time to be reduced by two to three orders of magnitude [85].

5.2. Reacting Channel Flows

In chemical microprocess technology one class of reactor designs deserves the term "generic", since many of the microreactors reported in the literature are based on this design concept. The design comprises at least one rectangular microchannel, often a multitude thereof, with a solid catalyst attached to the channel walls. The reacting fluid flows through the channel, while the reagents diffuse to the channel wall where they undergo chemical reactions. There are two versions of this design concept (Fig. 20). Either a smooth surface, often a metal layer, acts as catalyst, or the reaction occurs in a catalytically active porous medium. Clearly, the advantage of the porous catalyst layer is the higher specific surface area offering more reaction sites to the reagents. However, fully coupled simulations of reaction – convection – diffusion processes in catalyst-coated channels are quite rare, so most of the studies reported in this section are based on the concept of wall-catalyzed reactions.

For the reasons described above, reaction – convection – diffusion problems tend to be difficult to solve numerically. Hence, the simulation of reacting flows in three dimensions or parameter studies of micro reaction devices may be very time consuming. To enable rapid prototyping of microreactors, efficient modeling strategies with a minimum expenditure of computational resources are needed. The modeling approach developed in [86] allows a limited class of reacting microchannel flows to be assessed very quickly. It assumes a microchannel of length L and depth h with a first-order reaction occurring at one of the channel walls (Fig. 21). In cases where the flow profile is independent of the axial position in the channel and the problem can be approximated by a two-dimensional model, the mass transport equation for a chemical species a can be written in dimensionless form as

$$\frac{\mathrm{Pe}\,h}{L}u\left(\eta\right)\frac{\partial c_\mathrm{a}}{\partial\zeta}=\frac{\partial^2 c_\mathrm{a}}{\partial\eta^2} \tag{39}$$

where the axial and transverse coordinates ζ and η were nondimensionalized by the channel length L and the channel depth h. The reactant concentration is denoted by c_a, the velocity by u, and the Péclet number is expressed by the average velocity $\bar{u}$ and the diffusion constant D as $\mathrm{Pe}=\bar{u}\,h/D$. Equation 39 is solved subject to the boundary conditions of an impermeable upper channel wall and a first-order reaction with rate constant k occurring at the lower channel wall.

Figure 20. Reaction channels with a smooth surface (left) and a porous medium (right) as catalyst

Such a first-order reaction term surely does not adequately capture the mechanism of heterogeneous catalysis, but it may be a reasonable approximation of the kinetics in a limited parameter or operation range. An important dimensionless group characterising the reactive flow is the Damköhler number, defined as

$$\mathrm{Da}=\frac{kh}{D} \tag{40}$$

which characterizes the ratio of the diffusive and reactive timescales. The mass-transport equation has a separable solution of the form

$$c_\mathrm{a}\left(\zeta,\eta\right)=\bar{c}_\mathrm{a}\left(\zeta\right)f_\mathrm{a}\left(\eta\right), \tag{41}$$

where

$$\bar{c}_\mathrm{a}\left(\zeta\right)=\int_0^1 c_\mathrm{a}\left(\zeta,\eta\right)\mathrm{d}\eta. \tag{42}$$

By inserting this ansatz into Equation 39, the solution can be determined in form of an eigenfunction expansion [87]. The parameter controlling the number of terms of this expansion having to be taken into account is $Pe{\cdot}h/L$, which is usually of the order $0.01 - 1$ in microreactors. For this reason, often only the first term contributes. With the entrance condition $\bar{c}_\mathrm{a}\left(\zeta\right)=1$ the axial dependence can then be written as

$$\bar{c}_\mathrm{a}\left(\zeta\right)=\exp\left(-\lambda_\mathrm{a}\zeta\right), \tag{43}$$

where the eigenvalue λ_a is given as the solution of a nonlinear algebraic equation. Comparing the analytical results to full numerical simulations showed good agreement [86]. In addition to isothermal flows, analytical solutions were also determined for nonisothermal reacting flows and the model extended to second-order kinetics. Thus, a class of models was developed which may provide a simple characterization of reacting flows in microchannels without the need to do a full numerical simulation.

A similar analytical model for reacting flows in microchannels was used to assess the quality of simple plug-flow models which may be used to estimate reaction rate constants [88]. Microreactors lend themselves to measuring intrinsic rate constants of chemical reactions as, due to the short diffusion paths, heat and mass transfer limitations can be eliminated. The simplest way to deduce the rate constant k of a first-order heterogeneously catalyzed reaction at the walls of a tube is by assuming the reaction to occur in the volume of a plug-flow reactor. In this way the wall reaction is replaced by a pseudohomogeneous reaction and the velocity profile of the flow is ignored, which means that effectively a one-dimensional model is used. By measuring the inlet and outlet concentration of the reacting component, the rate constant is then obtained as

$$k=\frac{\bar{u}\,R}{2L}\ln\left(\frac{c_\mathrm{a}\left(\zeta=1\right)}{c_\mathrm{a}\left(\zeta=0\right)}\right). \tag{44}$$

where the notation is chosen similar to the previous paragraph, and L and R are the length and radius of the tube, respectively. Two effects are not taken into account by this expression. First, radial concentration gradients are ignored. Second, dispersion in the tube as discussed in Section 4.4 is neglected.

The one-dimensional model of reacting flows was extended to include Taylor – Aris dispersion [88] by considering an equation of the form

$$\frac{\mathrm{d}^2c_\mathrm{a}}{\mathrm{d}\zeta^2}-\frac{\mathrm{Pe}^*}{2}\frac{\mathrm{d}c_\mathrm{a}}{\mathrm{d}\zeta}-\beta c_\mathrm{a}=0, \tag{45}$$

where Pe^* is a modified Péclet number containing the Taylor – Aris dispersion constant instead of the diffusivity, and β a dimensionless parameter representing the pseudohomogeneous reaction. To study the influence of dispersion on chemical conversion, the solution of Equation 45 was compared to the solution of the corresponding two-dimensional problem, obtained in a similar way as sketched in the previous paragraph. It turned out that for a

Figure 21. Two-dimensional model geometry of a microchannel with a reaction occurring at the lower channel wall

Damköhler number of 1, no satisfactory agreement between the one- and the two-dimensional models was achieved. The inclusion of Taylor – Aris dispersion improved the concentration profiles to a certain degree with respect to a plug-flow model, but the main reason for the deviations are the radial concentration gradients, which are not accounted for in the one-dimensional models. Hence, when attempting to extract intrinsic reaction-rate constants from comparisons of experimental results with results of one-dimensional reactor models, care should be taken to work in a regime of Damköhler numbers significantly smaller than 1.

5.3. Heat-Exchanger Reactors

The design of multichannel microreactors for gas-phase reactions is typically based on a stack of microstructured platelets. For strongly endothermic or exothermic reactions, it lends itself to alternate between layers of reaction channels and heating or cooling gas channels which supply energy to or withdraw it from the reaction. Such a set up is similar to the heat exchanger design depicted in Figure 9. Within this class of microreactor designs a choice can be made between different flow schemes of the gas streams in adjacent layers (co-, counter- or cross-current). The countercurrent coupling of an endothermic reaction to a heating gas stream in a multilayer architecture was studied [41] for a 2D model (Figure 22).

The dynamics of a heterogeneously catalyzed gas-phase reaction occurring in a nanoporous medium in combination with heat and mass transfer was simulated using a finite-volume approach. In contrast to other studies of similar type, heat and mass transfer in the nanoporous medium were explicitly accounted for by solving volume-averaged transport equations in the porous medium. Such an approach made it possible to compare the transport resistances in the gas phase and in the porous medium and to study the trade-off between maximization of catalyst mass and minimization of mass-transfer resistance due to pore diffusion. A typical concentration profile of a reacting chemical species which is converted by the catalyst is displayed in Figure 23. Due to the small pore size with an average diameter of 40 nm, the effective diffusivity in the porous medium is quite small and large concentration gradients build up, whereas in the microchannel the gradients are negligible. Typical catalyst effectiveness factors for a 100 µm catalyst layer were found to be of the order of 0.4. One of the outstanding potentials of microreactors is efficient utilization of the catalyst material. In conventional fixed-bed technology, catalyst pellets for liquid reactions are usually of a size of 2 – 5 mm [79]. Due to diffusive limitations in such comparatively large pellets, reactions often occur in a region close to the surface.

Figure 22. 2D model of a countercurrent heat-exchanger reactor with a nanoporous catalyst layer deposited on the channel wall

Figure 23. Normalized concentration profile of a reacting species across a microchannel of 500 µm width with a 100 µm catalyst layer deposited on the wall

A main objective of [41] was to study the influence of heat transfer on the achievable molar flux per unit reactor volume of the product species. Unstructured channels were compared to channels containing microfins. Heat-transfer enhancement due to microfins resulted in a different axial temperature profile with a higher outlet temperature in the reaction gas channel. Due to this effect and by virtue of the temperature dependence of the reaction rate, an improvement of heat transfer resulted in a significantly higher specific product molar flux. For the system under study, the heat-transfer enhancement achievable with microfins was found to increase the specific molar flux by about a factor of two. Such model studies show that a complex interplay between flow, heat transfer, and mass transfer may occur in microreactors and underline the need for fully coupled simulations incorporating conjugate heat transfer and transport in porous media.

The optimization of heat transfer in a heat-exchanger reactor was also the objective of [89]. Specifically, the exothermic water gas shift (WGS) reaction

$$CO + H_2O \leftrightarrow H_2 + CO_2 \tag{46}$$

which is utilized in fuel reformers to reduce the level of carbon monoxide, was considered. When the temperature of an exothermic, reversible reaction such as the WGS reaction increases, the kinetics are accelerated but the equilibrium is shifted more towards the feed components. Due to this fact, neither very low nor very high temperatures are optimal when the goal is to maximize the space – time yield for a given conversion. Rather, there is a specific temperature trajectory, i.e., a specific functional dependence of the reaction temperature on time, which allows maximization of the space – time yield. Due to their short thermal diffusion paths, microreactors allow the temperature profile in a reaction channel to be controlled much better than conventional equipment.

A counter-current heat-exchanger reactor for the WGS reaction with integrated cooling gas channels for removal of the reaction heat was analyzed [89]. The computational domain of the 2D model on the basis of the finite-element method is sketched in Figure 24. The reactor design does not allow for detailed adjustment of the temperature profile in the reaction gas channel, but by varying the cooling gas inlet temperature and the ratio of cooling gas and reaction gas flow rate, different temperature profiles can be imposed.

The reaction dynamics studied in the simulations is such that by release of reaction heat close to the inlet, the reaction gas temperature rises considerably. Owing to the fast kinetics at high temperatures, much of the CO conversion is already achieved in the inlet region. The remaining conversion is then mainly due to a reduction of the temperature and the corresponding shift in chemical equilibrium. This part of the process requires a large channel length. Thus, even minor differences in conversion achievable by improved temperature control may result in a considerable reduction of reactor size and the required amount of catalyst. When considering more advanced reactor designs allowing for fine-tuning of the temperature trajectory, CFD simulations are indispensable for performance optimization.

6. Conclusion and Outlook

The discussion of modeling and simulation techniques for microreactors shows that the toolbox available at present is quite diverse and goes well beyond the standard capabilities of CFD methods available in commercial solvers. In microreactors special methods needed for the modeling of noncontinuum physics play only a minor role, and most of the effects are described by the

Figure 24. Model of a counter-current heat-exchanger reactor for exothermic reactions. The dashed lines indicate symmetry planes

standard continuum equations. However, even if the laminar nature of the flow somehow reduces the difficulty of simulation problems compared to macroscopic flows, there are a number of problems which are extremely difficult and require very fine computational grids. Among these problems is the numerical study of mixing in liquids, which often severely suffers from discretization artefacts.

A subject of growing importance which has not been discussed in this overview due to space limitations is modeling and simulation of multiphase microflows. Macroscopic multiphase flows are often modeled by using an Euler – Euler formulation of interpenetrating continua, that is, a volume-averaged description where phase boundaries are no longer explicitly resolved. When the spatial extension of bubbles or droplets becomes comparable to the channel dimensions, the gas – liquid or liquid – liquid interfaces must be modeled explicitly. There are methods available for such kinds of problems (e.g. the volume-of-fluid method) which are, however, computationally much more expensive than the Euler – Euler formulations employed for macroscopic flows. It is not only for the computational requirements that the predictive power of multiphase microflow computations is much lower than that of their counterparts for single-phase flow. As an example, moving contact lines are relevant for gas – liquid flows, and in some cases flow is accompanied by phase-change phenomena. Both the motion of a gas – liquid – solid contact line and the evaporation of liquid heavily depend on complex transport phenomena in the close vicinity of the contact-line region which are only partially understood until now. Consequently, the simulation of such phenomena as flow boiling in microchannels is in its infancy and its predictive power is very limited. Such examples underline the necessity of further research on multiphase microflows. Currently, corresponding numerical schemes are available, but the models do not adequately account for the boundary conditions at the contact line.

A further topic which has not been discussed in this overview and which is only beginning to evolve refers to system-level simulations of microprocess devices. In conventional process technology there is often an interplay between detailed CFD and system-level simulations of physicochemical processes. Owing to their large computational requirements, CFD methods can usually not be employed for the simulation of chemical reactors or plants consisting of a number of different subunits. Rather, CFD results enter into system models which treat the subunits in a simplified manner by just referring to characteristic curves specifying input – output behavior. In such a way, the flow in a pipe, for example, is characterized by a flow rate as a function of applied pressure difference. In conventional process technology a library of component models already exists which may be further extended and refined by incorporating the results of CFD simulations. However, in microprocess technology such system-level approaches do not yet seem to have been developed to an appreciable degree. A natural step for the further development of modeling and simulation techniques for microreactors would be to formulate system-level models which allow coupling to CFD simulations. In such a way also the commercial application of microreactors could gain additional impetus, as system-level models would allow fast evaluation of processes unparalleled by the comparatively time-consuming approaches presently available.

Benzofurans

GERD COLLIN, Rütgerswerke AG, Duisburg, Germany
HARTMUT HÖKE, Rütgerswerke AG, Duisburg, Germany

1. Benzofuran 1
2. Dibenzofuran 1
3. References 3

1. Benzofuran

Benzofuran [*271-89-6*], coumarone, C_8H_6O, was obtained by R. FITTIG and G. EBERT in 1882, by calcining coumarilic acid (from coumarin) with lime. In 1890, G. KRAEMER and A. SPILKER discovered benzofuran in coal tar.

Physical Properties. Benzofuran, M_r 118.14, *bp* (101.3 kPa) 171.4 °C, *mp* −28.9 °C, ϱ (20 °C) 1.0948 g/cm^3, is a colorless liquid with an aromatic odor; it is volatile in steam, soluble in ethanol, and insoluble in water.

Chemical Properties. Benzofuran polymerizes slowly at ambient temperature, more rapidly with heat and in the presence of an acidic catalyst; it is resistant to aqueous alkali.

Production. Coal tar contains ca. 0.01 % benzofuran, which can be concentrated through distillation to ca. 15 % in a light oil fraction with a boiling range of 165–175 °C. It is recovered either by precipitation as the dibromide or the picrate, or by sulfonation in acetic anhydride, followed by decomposition of the benzofuran derivatives. If the benzofuran fraction is largely free from indene, benzofuran can be concentrated further through either selective extraction or azeotropic distillation with alkylene glycols.

Benzofuran can be synthesized by dehydrogenation and cyclization of 2-ethylphenol.

Uses. Benzofuran, together with indene, is the raw material used for the production of indene–coumarone resins (→) from light oil fractions of coal tar. Normal commercial resins contain up to 10 % benzofuran polymers. No large-scale commercial use has been found for pure benzofuran.

Toxicology and Occupational Health. Benzofuran showed acute toxic effects in rabbits when administered orally at a dosage of 1 g [8]. The LD_{50} (mice, intraperitoneal) is 500 mg/kg [9]. (A carcinogenicity study on benzofuran in rats and mice was performed in the United States under the National Toxicology Program. The results have not yet been published [10].)

2. Dibenzofuran

Dibenzofuran [*132-64-9*], diphenylene oxide, $C_{12}H_8O$, was synthesized for the first time by C. LESIMPLE in 1866 from triphenyl phosphate and lime; its constitution was recognized in 1871 by W. HOFFMEISTER, and it was found in coal tar by G. KRAEMER and R. WEISSGERBER in 1901.

Physical Properties. Dibenzofuran, M_r 168.18, *bp* (101.3 kPa) 287 °C, ϱ(99.3 °C) 1.0886 g/cm^3, *mp* 82.8 °C (a higher melting point indicates impurities of fluorene or acenaphthene), consists of colorless crystals with

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.l03_l01

a weak, characteristic odor. It is resistant for a short time in an inert atmosphere to >600 °C. Dibenzofuran is volatile in steam; sublimable; readily soluble in diethyl ether, benzene, and acetic acid; fairly soluble in ethanol; insoluble in water; its enthalpy of vaporization (130–140 °C) is 66.4 kJ/mol, enthalpy of combustion 5882 kJ/mol, dielectric constant (100 °C) 3.0, and dipole moment (liquid) 0.9 D.

Chemical Properties. The skeleton of the dibenzofuran molecule combines that of both biphenyl and diphenyl ether. In comparison with biphenyl, the reactivity of dibenzofuran to electrophilic substitution is lower. The 2- and 2,8-derivatives can be prepared by halogenation, sulfonation, Friedel–Crafts reaction, Gattermann's aldehyde synthesis, and chloromethylation; the 3- and 3,8-derivatives are obtained by nitration; the 4- and 4,6-positions exclusively by metalation and mercuration. In the 1-position, substituted derivatives can be formed only by indirect methods or by radical substitution. If dibenzofuran is already substituted, this substituent determines whether a new substituent is homonuclear, i.e., in the same ring (e.g., hydroxyl, amino, ether groups), or heteronuclear (e.g., halogen, nitro, acyl groups). Examples of opening the furan nucleus include fusion with potassium hydroxide at 280–300 °C to give 2,2′-dihydroxybiphenyl, reaction with potassium metal to form 2-hydroxybiphenyl, or conversion to phenol with aluminum chloride at 140 °C.

Production. Dibenzofuran is present in coal tar at a level of ca. 1 %. It is recovered from a wash oil fraction that boils between 275 and 290 °C (containing ca. 30 % dibenzofuran). A redistillation step is largely successful in separating dibenzofuran from acenaphthene, which boils 7 °C lower. The technically pure compound is obtained through crystallization of the redistilled fraction. In admixture with ca. 60 % acenaphthene, dibenzofuran forms a eutectic and, with fluorene, which boils about 13 °C higher, a continuous series of mixed crystals [11].

Dibenzofuran can be synthesized by dehydrogenation of phenol at 450 °C [12]; by oxidative dehydrogenation of phenol and cyclization of 2-cyclohexenylcyclohexanone [13]; by cyclization of diphenyl ether in the presence of palladium(II) acetate [14]; or by the pyrolysis of phthalic anhydride with furan [15]. As sufficient quantities of dibenzofuran can be produced from coal tar, these syntheses are not industrially applied. Some dibenzofuran derivatives can be synthesized better by ring closure than by substitution of dibenzofuran.

Uses. Due to its high heat resistance, dibenzofuran, together with biphenyl (→), is a component of heat-transfer oils. When combined with methylnaphthalenes, it is suitable as a carrier for dyeing and printing textiles [16]. Some of its derivatives serve as intermediates for naphtol AS (→) and chromium complex dyes, e.g., 2,2′-dihydroxybiphenyl (→) and 2-hydroxydibenzofuran-3-carboxylic acid (from 2-hydroxydibenzofuran through Kolbe–Schmitt carboxylation).

Derivatives of dibenzofuran phosphonic acid can be used as antioxidants in plastics [17]. A range of polymers can be produced from dibenzofuran, e.g., heat-resistant polyarylacetylene [18] and quinoxaline polymers [19] or photoconductive polymers for electrophotography [20]. Dibenzofuroyl silicon polymers and monomers can be employed as perfume oil bases, in cosmetics, and as fluids for the production of elastomers and resins [21]. Dibenzofuran derivatives have been proposed as pharmaceuticals, e.g., dibenzofuranyl aminoalcohols as sedatives and tranquilizers [22] and dibenzofurylpropionic acid and derivatives as antiphlogistics [23].

Toxicology and Occupational Health. Dibenzofuran caused no adverse effects when fed to rats at high dosage for 200 d (0.025–0.4 % of feed) [24]. In skin- and eye-irritant tests (24-h exposure, FDA method), dibenzofuran proved to be nonirritating [25]. On exposure of fish (mullet sp.) to 750 μg/L for 6 and 24 d, dibenzofuran caused weak biochemical stress responses in brain, interrenal gland, and liver. This dosage was one-third the one-week LC_{50} level [26, 27]. Dibenzofuran is degraded by microbes [28, 29]. The microbial fate of benzofuran is unknown [30], although it is metabolized in mammals (rats) by oxidation, followed by conjugation with sulfate and excretion in urine [8]. No TLV has been stipulated for either substance.

1. Introduction

The preservation and management of our diverse resources are fundamental political tasks to foster sustainable development in the 21st century. Sustainable economic growth requires safe and sustainable resources for industrial production, a long-term and confident investment and finance system, ecological safety, and sustainable life and work perspectives for the public. Fossil resources are not regarded as sustainable, however, and their availability is more than questionable in the long-term. Because of the increasing price of fossil resources, moreover, the feasibility of their utilization is declining.

It is, therefore, essential to establish solutions which reduce the rapid consumption of fossil resources, which are not renewable (petroleum, natural gas, coal, minerals). A forward looking approach is the stepwise conversion of large parts of the global economy into a sustainable biobased economy with bioenergy, biofuels, and biobased products as its main pillars (Fig. 1).

Whereas for energy production a variety of alternative raw materials (wind, sun, water, biomass, nuclear fission and fusion) can be established, industry based on conversion of sustainable material, for example the chemical industry, industrial biotechnology, and also the fuel generation, depends on biomass, in particular mainly on plant biomass.

Figure 1. 3-Pillar model of a future biobased economy

Some change from the today's production of goods and services from fossil to biological raw materials will be essential. The rearrangement of whole economies to implement biological raw materials as a source with increased value requires completely new approaches in research and development. On the one hand, biological and chemical sciences will play a leading role in the generation of future industries in the 21st century. On the other hand, new synergies of biological, physical, chemical, and technical sciences must be elaborated and established. This will be combined with new traffic technology, media- and information technology, and economic and social sciences. Special requirements will be placed on both the substantial converting industry and research and development with regard to raw material and product line efficiency and sustainability.

The development of substance-converting basic product systems and polyproduct systems, for example biorefineries, will be the "key for the access to an integrated production of food, feed, chemicals, materials, goods, and fuels of the future" [4].

2. Historical Outline

2.1. Historical Technological Outline and Industrial Resources

Today's biorefinery technologies are based (1) on the utilization of the whole plant or complex biomass and (2) on integration of traditional and modern processes for utilization of biological raw materials. In the 19th and the beginning of the 20th century large-scale utilization of renewable resources was focused on pulp and paper production from wood, saccharification of wood, nitration of cellulose for guncotton and viscose silk, production of soluble cellulose for fibers, fat curing, and the production of furfural for Nylon. Furthermore, the technology of sugar refining, starch production, and oil milling, the separation of proteins as feed, and the extraction of chlorophyll for industrial use with alfalfa as raw material were of great historical importance. But also processes like wet grinding of crops and biotechnological processes like the production of ethanol, acetic acid, lactic acid, and citric acid used to be fundamental in the 19th and 20th century.

2.2. The Beginning – A Digest

2.2.1. Sugar Production

The history of industrial conversion of renewable resources is longer than 200 years. Utilization of sugar cane has been known in Asia since 6000 BC and imports of cane sugar from oversea plantations have been established since the 15th century. The German scientist A. S. Marggraf was a key initiator of the modern sugar industry. In 1748 he published his research on the isolation of crystalline sugar from different roots and beet [5, 6]. Marggraf's student, F. C. Achard, was the first to establish a sugar refinery based on sugar beet, in Cunern/Schlesien, Poland, in 1801.

2.2.2. Starch Hydrolysis

In 1811, the German pharmacist G. S. C. Kirchhoff found that when potato starch was cooked in dilute acid the starch was converted into "grape sugar" (i.e., *d*-glucose or dextrose) [7]. This was not only a very important scientific result but also the starting point of the starch industry. In 1806 the French emperor Napoleon Bonaparte introduced an economic continental blockade which considerably limited overseas trade in cane sugar. Thus, starch hydrolysis became of interest for the economy. The first starch sugar plant was established in Weimar, Germany, in 1812, because of a recommendation

of J. W. Döbereiner to grand duke Carl August von Sachsen-Weimar. Successful development of the sugar beet industry, however, initially obstructed further development of the starch industry [8]. In 1835, the Swedish Professor J. J. Berzelius developed enzymatic hydrolyses of starch into sugar and introduced the term "catalysis".

2.2.3. Wood Saccharification

In 1819 the French plant chemist H. Braconnot discovered that sugar (glucose) is formed by treatment of wood with concentrated sulfuric acid. 1855, G. F. Melsens reported that this conversion can be carried out with dilute acid also. Acid hydrolysis can be divided into two general approaches, based on (1) concentrated acid hydrolysis at low temperature and (2) dilute acid hydrolysis at high temperature. Historically, the first commercial processes, named wood saccharification, were developed in 1901 by A. Classen (Ger. Patent 130980), employing sulfuric acid, and in 1909 by M. Ewen and G. Tomlinson (US Patent 938208), working with dilute sulfuric acid. Several plants were in operation until the end of World War I. Yields of these processes were usually low, in the range 75–130 liter per ton wood dry matter only [9, 10]. Technologically viable processes were, however, developed in the years between World War I and World War II. The German chemist Friedrich Bergius was one of the developers. The sugar fractions generated by wood hydrolyses have a broad spectrum of application. An important fermentation product of wood sugar of increasing interest is ethanol. Ethanol can be used as fuel either blended with traditional hydrocarbon fuel or as pure ethanol. Ethanol is also an important platform chemical for further processing [11].

2.2.4. Furfural

Dübereiner was the first to report the formation and separation of furfural by distillation of bran with diluted sulfuric acid in 1831. In 1845 the English Chemist G. Fownes proposed the name "furfurol" (furfur–bran; oleum–oil). Later the suffix "ol" was changed to "al" because of the aldehyde function [12, 13].

Treatment of hemicellulose-rich raw materials with dry steam in the presence of hydrogen chloride gave especially good results [14]. Industrial technology for production of furfural from pentose is based on a development of an Anglo-American company named Quaker Oats. The process was been developed in the nineteen-twenties [E.P. 203691 (1923), F.P. 570531 (1923)]. Since 1922 Quaker Oats Cereal Mill in Cedar Rapids/Iowa, USA, has produced up to 2.5 tons of furfural per day from oat husks. Since 1934 the process had been established as an industrial furfural plant. Furfural was the cheapest aldehyde, at 16–17 cents per lb (lb=pound; 1 metric ton=1000 kg=2204.62442 lb; 1 kg=0.453592 lb) [15]. Until approximately 1960 DuPont used furfural as a precursor of nylon-6.6. Furfural has since been substituted by fossil based precursors.

2.2.5. Cellulose and Pulp

In 1839 the Frenchman A. Payen discovered that after treatment of wood with nitric acid and subsequent treatment with a sodium hydroxide solution a residue remained which he called "les cellules", cellulose [16]. In 1854 caustic soda and steam were used by the Frenchman M. A. C. Mellier to disintegrate cellulose pulp from straw. In 1863 the American B. C. Tilgham registered the first patent for production of cellulose by use of calcium bisulfite. Together with his brother, Tilgham started the first industrial experiments to produce pulp from wood by treatment with hydrogen sulfite. This was 1866 at the paper mill Harding and Sons, Manayunk, close to Philadelphia. In 1872 the Swedish Engineer C. D. Ekman was the first to produce sulfite cellulose by using magnesium sulfite as cooking agent [17]. By 1900 approximately 5200 pulp and paper mills existed worldwide, most in the USA, approximately 1300 in Germany, and 512 in France.

2.2.6. Levulinic Acid

In 1840 the Dutch Professor G. J. Mulder (who also introduced the name "protein") synthesized levulinic acid (4-oxopentanoic acid, c-ketovaleric acid) by heating fructose with hydrochloride for the first time. The former term

"levulose" for fructose gave the levulinic acid its name [18]. Although levulinic acid has been well known since the 1870s when many of its reactions (e.g., esters) were established, it has never reached commercial use in any significant volume. In the 1940s commercial levulinic acid production was begun in an autoclave in the United States by A. E. Staley, Dectur, Illinois [19]. At the same time utilization of hexoses from low-cost cellulose products was examined for the production of levulinic acid [20]. As early as 1956 levulinic acid was regarded as a platform chemical with high potential [21].

2.2.7. Lipids

From 1850 onward European import of tropical plant fats, for example palm-oil and coconut oil, started. Together with the soda process, invented by the French N. Leblanc in 1791, the industrialization of the soap production began and soap changed from luxury goods into consumer goods. The developing textile industry also demanded fat based products. In 1902 the German chemist W. Normann discovered that liquid plant oils are converting into tempered fat by augmentation of hydrogen. Using nickel as catalyst Norman produced tempered stearic acid by catalytic hydration of liquid fatty acids [22]. The so called "fat hardening" led to the use of European plant oils in the food industry (margarine) and other industries.

2.2.8. Vanillin from Lignin

In 1874 the German chemists W. Haarmann and F. Tiemann were the first to synthesize vanillin from the cambial juice of coniferous wood. In 1875 the company Haarmann and Reimer was founded. The first precursor for the production of vanillin was coniferin, the glucoside of coniferyl alcohol. This precursor of lignin made from cambial juice of coniferous trees was isolated, oxidized to glucovanillin, and then cleaved into glucose and vanillin [23]. This patented process [24] opened the way to industrial vanillin production. It was also the first industrial utilization of lignin. Besides the perfume industry, the invention was of great interest to the upcoming chocolate industry. Later, however, eugenol (1-allyl-4-hydroxy-3-methoxybenzene), isolated from clove oil, was used to produce vanillin. Today, vanillin production is based on lignosulfonic acid which is a side product of wood pulping. The lignosulfonic acid is oxidized with air under alkaline conditions [25, 26].

2.2.9. Lactic Acid

In 1895 industrial lactic acid fermentation has been developed by the pharmaceutical entrepreneur A. Boehringer. The Swedish pharmacist C. W. Scheele had already discovered lactic acid in 1780 and the conversion of carbohydrates into lactic acid had been known for ages in food preservation (e.g. Sauerkraut) or agriculture (silage fermentation). Because of the activity of Boehringer the German company Boehringer-Ingelheim can be regarded as the pioneer of industrial biotechnology. Both the process and the demand for lactic acid by dyeing factories, and the leather, textile, and food industries made the company the leading supplier. In 1932 W. H. Carothers, who was also the inventor of polyamide-6.6, developed, together with van Natta, a polyester made from lactic acid, poly(lactic acid) [27]. In the late 1990s this poly(lactic acid) was commercialized by the company NatureWorks (Cargill, the former Cargill Dow) [28].

2.3. The Origins of Integrated Biobased Production

In the year 1940 the German chemist P. von Walden (noted for his "Inversion of configuration at substitution reactions", the so-called "Walden-Reversion") calculated that in 1940 Germany produced $13 \cdot 10^6$ t of cellulose leaving 5 to 6 million tons of lignin suitable only as wastage. He then formulated the question: How long can national economy tolerate this [29]? Approaches to integrated production during industrial processing of renewable primary products have a long tradition, starting from the time when industrial cellulose production expanded continuously, as also did the related waste-products. Typical examples of this will be mentioned.

As early as 1878 A. Mitscherlich, a German chemist, started to improve the sulfite pulp process by fermentation of sugar to ethyl alcohol — it should be mentioned that sugar is a substance in the waste liquor during sulfite pulp production. He also put into practice a procedure to obtain paper glue from the waste liquor. Both processes were implemented in his plant located in Hof, Germany, in the year 1898 [30].

In 1927 the American Marathon Corporation assigned a group of chemists and engineers to the task of developing commercial products from the organic solids in the spent sulfite liquor from the Marathon's Rothschild pulp and paper operations close to Wausau, Wisconsin, USA. The first products to show promise were leather tanning agents. Later, the characteristics of lignin as dispersing agents became evident. By the mid 1930s, with a considerable amount of basic research accomplished, Marathon transferred operations from a research pilot plant to full-scale production [31].

One of the most well known examples is the production of furfural by the Quaker Oats Company since 1922, thus coupling food, i.e. oat flakes, production and chemical products obtained from the waste [13] (see 2.2). On the basis of furfural a whole section of chemical production developed — furan chemistry.

Agribusiness, especially, strived to achieve combined production from the very beginning. Modern corn refining started in the middle of the 18th century when T. Kingsford commenced operation of his corn refining plant in Oswego, New York [32]. Corn refining is distinguished from corn milling because the refining process separates corn grain into its components, for example starch, fiber, protein and oil, and starch is further processed into a substantial number of products [33].

The extensive usage of green crops has been aim of industry for decades, because there are several advantages. Particularly worthy of mention is the work of Osborn (1920) and Slade and Birkinshaw (1939) on the extraction of proteins from green crops, for example grass or alfalfa [34].

In 1937 N.W. Pirie developed the technical separation and extraction methods needed for this use of green crops [35, 36]. By means of sophisticated methods all the botanical material should have been used, both for production of animal feed, isolated proteins for human nutrition, and as raw material for further industrial processes, for example glue production. The residual material, juices rich in nutrients, had initially been used as fertilizer; later they were used for generation of fermentation heat based on biogas production [37, 38].

These developments resulted in market-leading technology, for example the Proxan and Alfaprox procedures, used for generation of protein–xanthophyll concentrates, including utilization of the by-products, however, predominantly in agriculture [39].

In the United States commercial production of chlorophyll and carotene by extraction from alfalfa leaf meal had started in 1930 [40, 41]. For example Strong, Cobb and Company produced 0.5 t chlorophyll per day from alfalfa as early as 1952. The water-soluble chlorophyll, or chlorophyllin, found use as deodorizing agent in toothpastes, soaps, shampoos, candy, deodorants, and pharmaceuticals [42].

A historical important step for today's biorefinery developments was the industry-politics-approach of "Chemurgy", founded in 1925 in the US by the chemist W.J. Hale, son-in-law of H. Dow, the founder of Dow Chemical, and C. H. Herty, a former President of the American Chemical Society. They soon found prominent support from H. Ford and T. A. Edisons. Chemurgy, an abbreviation of "chemistry" and "ergon", the Greek word for work [43], means by analogy "chemistry from the acre" that is the connection of agriculture with the chemical industry.

Chemurgy was soon shown to have a serious industrial political philosophy — the objective of utilizing agricultural resources, nowadays called renewable resources, in industry. There have been common conferences between agriculture, industry, and science since 1935 with a national council called the "National Farm Chemurgic Council" [44]. The end of Chemurgy started with the flooding of the world market with cheap crude oil after World War II; numerous inventions and production processes remained, however, and are again highly newsworthy. One was a car, introduced by Henry Ford 1941, whose car interior lining and car body consisted 100 % of bio-synthetics; to be specific it had been made from a cellulose meal, soy meal, formaldehyde resin composite material in the

proportions 70 %:20 %:10 %, respectively. The alternative fuel for this car was pyrolysis methanol produced from cannabis. Throughout the thirties more than 30 industrial products based on soy bean were created by researchers from the Ford company; this made it necessary to apply complex conversion methods [45]. Hale was a pioneer of ethyl alcohol and hydrocarbon fuel mixture (power alcohol, gasohol) [46]. This fuel mixture, nowadays called E10-fuel, consisting of 10 % bioethanol and 90 % hydrocarbon-based fuel, has been the national standard since the beginning of this millennium in the United States.

Associated with the work of Bergius, 1933 [47], and Scholler, 1923 and 1935 [48, 49], wood saccharification was reanimated at the end of World War II. Beside optimization of the process, use of lignocelluloses was of great interest. The continuously growing agribusiness left behind millions of tons of unused straw. Two Americans, Othmer and Katzen, were the main pioneers in the field of wood saccharification [50]. Between the years 1935 and 1960 several hydrolysis plants were built in Germany and the United States; in these deal, wood flour, surplus lumber, and also straw were hydrolyzed [51]. One of the most well known plants are those of Scholler/Tornesch located in Tornesch, Germany, with a production rate of 13,000 t/a, in Dessau, Germany, production rate 42,000 t/a, based on wood, in Holzminden, Germany, production rate of 24,000 t/a, also based on wood, in Ems, Switzerland, with a production rate of 35,000 t/a, also wood based, and the plants in Madison and Springfield, United States, and the Bergius plants in Rheinau, Germany (Rheinau I, built 1930, with a production rate of 8000 t/a, based on surplus lumber; Rheinau II, built 1960 with a production rate of 1200 t/a, based on wood) and the plant in Regensburg, Germany, with a production rate of 36,000 t/a [52].

During World War II the plant in Springfield, Oregon, US (using the Scholler-Tornesch process as modified by Katzen) produced 15,000 gallons of ethyl alcohol per day from 300 t wood flour and sawdust, i.e. 50 gallons per ton of wood [53]. The plant in Tornesch, Germany, has been producing approximately 200 liters of ethyl alcohol, purity 100 %, per ton wood and approximately 40 kg yeast per ton of wood. In 1965 there were 14 plants in the former Soviet Union, with a total capacity of 700,000 t/a and an overall annual wood consumption of 4×10^6 t [9].

During the nineteen-sixties wood chemistry had its climax. Projects had been developed, which made it possible to produce nearly all chemical products on the basis of wood. Examples are the complex chemical technological approaches of wood processing from Timell 1961 [54], Stamm 1964 [55], James 1969 [56], Brink and Pohlmann 1972 [57], and the wood-based chemical product trees by Oshima 1965 [58]. Although these developments did not make their way into industrial production, they are an outstanding platform for today's lignocellulose conversions, product family trees, and LCF biorefineries (5.2).

Most of the above mentioned technologies and products, some of which were excellent, could not compete with the fossil-based industry and economy; nowadays, however, they are prevailing again. The basis for this revival started in the seventies, when the oil crisis and continuously increasing environmental pollution resulted in a broad awareness that plants could be more than food and animal feed. At the same time the disadvantages of intensive agricultural usage, for example over-fertilization, soil erosion, and the enormous amounts of waste, were revealed. From this situation developed complex concepts, which have been published, in which the aim was, and still is, technological and economical cooperation of agriculture, forestry, the food-production industry, and conventional industry, or at least consideration of integrated utilization of renewable resources.

Typical examples of this thinking were:

- integrated industrial utilization of wood and straw [59];
- industrial utilization of fast growing wood-grass [60, 61];
- complex utilization of green biomass, for example grass and alfalfa, by agriculture and industry [62 – 64];
- corn wet-grinding procedures with associated biotechnological and chemical product lines [65];
- modern aspects of thermochemical biomass conversion [66];
- discussion of the concept "organic chemicals from biomass" with main focus on biotechnological methods and products (white biotech-

nology) [67 – 69] and industrial utilization of biomass [70].

These rich experiences of the industrial utilization of renewable resources, new agricultural technology, biotechnology, and chemistry, and the changes in ecology, economics, and society led inevitably to the topic of complex and integrated substantial and energy utilization of biomass and, finally, to the biorefinery.

3. Situation

3.1. Some Current Aspects of Biorefinery Research and Development

Since the beginning of the 1990s the utilization of renewable resources for production of non-food products has fostered research and development which has received increasing attention from industry and politicians [71 – 73]. Integrated processes, biomass refinery technology, and biorefinery technology have become object of research and development. Accordingly, the term "biorefinery" was established in the 1990s [4, 74 – 83]. The respective biorefinery projects are focused on the fabrication of fuels, solvents, chemicals, plastics, and food for human beings. In some countries these biorefinery products are made from waste biomass. At first the main processes in the biorefinery involved ethanol fermentation for fuels (ethanol-oriented biorefineries) [84 – 88], lactic acid (LA) fermentation [28, 89], propanediol (PDO) fermentation [90], and the lysine fermentation [91] especially for polymer production. The biobased polymers poly(lactic acid) [28], propandiol-derived polymers [92], and polylysine [91] have been completed by polyhydroxyalkanoates [93] and polymerized oils [94].

Many hybrid technologies were developed from different fields, for example bioengineering, polymer chemistry, food science and agriculture. Biorefinery systems based on cereals [95, 96], lignocelluloses [97, 98], and grass and alfalfa [38, 99], and biorefinery optimization tools are currently being developed [100, 101]. The integration of molecular plant genetics to support the raw material supply is currently being discussed intensely [102, 103].

Broin and Associates has begun the development of a second generation of dry mill refineries and E.I. du Pont de Nemours has developed an integrated corn-based biorefinery. In 2001 NatureWorks LCC (to Cargill, former Cargill Dow LLC) started the industrial production of PLA (PLA-oriented Biorefinery) on the basis of maize.

Biorefineries are of interest ecologically [104], economically, and to business, government, and politicians [105 – 110]. National programs [111, 112], biobased visions [113], and plans [114] have been developed and the international exchange of information is increasing, for example as a result, among others, of series of international congresses and symposia:

- BIO World Congress on Industrial Biotechnology and Bioprocessing [115];
- biomass conferences [116, 117];
- The Green and Sustainable Chemistry Congress [118];
- ACS Symposium Series and [119]
- the Biorefinica symposia series [120, 121].

Currently, biorefinery systems are in the stage of development world-wide. An overview of the main aspects, activity, and discussions is the content of this book. An attempt to systematize the topic "Biorefinery" will be presented below.

3.2. Raw Material Biomass

Nature is a permanently renewing production chain for chemicals, materials, fuels, cosmetics, and pharmaceuticals. Many of the biobased industry products currently used are results of direct physical or chemical treatment and processing of biomass, for example cellulose, starch, oil, protein, lignin, and terpenes. On one hand one must mention that because of the help of biotechnological processes and methods, feedstock chemicals are produced such as ethanol, butanol, acetone, lactic acid, and itaconic acid, as also are amino acids, e.g., glutaminic acid, lysine, tryptophan. On the other hand, only 6×10^9 t of the yearly produced biomass, $1.7-2.0 \times 10^{11}$ t, are currently used, and only 3 to 3.5 % of this amount is used in non-food applications, for example chemistry [122].

The basic reaction of biomass is photosynthesis according to:

Industrial utilization of raw materials from agriculture, forestry, and agriculture is only just beginning. There are several definitions of the term "biomass" [122]:

- the complete living, organic matter in our ecological system (volume/non-specific);
- the plant material constantly produced by photosynthesis with an annual growth of 170 billion tons (marine plants excluded);
- the cell-mass of plants, animals, and microorganism used as raw materials in microbiological processes.

Biomass is defined in a recent US program [111, 112]: "The term "biomass" means any organic matter that is available on a renewable or recurring basis (excluding old-growth timber), including dedicated energy crops and trees, agricultural food and feed crop residues, aquatic plants, wood and wood residues, animal wastes, and other waste materials."

For this reason it is essential to define biomass in the context of the industrial utilization. A suggestion for a definition of "industrial biomass" [111, 112] is: "The term "industrial biomass" means any organic matter that is available on a renewable or recurring basis (excluding old-growth timber), including dedicated energy crops and trees, agricultural food and feed crop residues, aquatic plants, wood and wood residues, animal wastes, and other waste materials usable for industrial purposes (energy, fuels, chemicals, materials) and include wastes and co-wastes of food and feed processing."

Most biological raw material is produced in agriculture and forestry and by microbial systems. Forestry plants are excellent raw materials for the paper and cardboard, construction, and chemical industries. Field fruits are a pool of organic chemicals from which fuels, chemicals, chemical products, and biomaterials are produced (Fig. 2), [72].

Figure 2. Products and product classes based on biological raw materials [81]

Advances in genetics, biotechnology, process chemistry, and engineering are leading to a new manufacturing concept for converting renewable biomass to valuable fuels and products, generally referred to as the biorefinery. The integration of agroenergy crops and biorefinery manufacturing technologies offers the potential for the development of sustainable biopower and biomaterials that will lead to a new manufacturing paradigm [2, 123].

Waste biomass and biomass of nature and agricultural cultivation are valuable organic reservoirs of raw material and must be used in accordance with their organic composition. During the development of biorefinery systems the term "waste biomass" will become obsolete in the medium-term [124].

3.3. National Vision and Goals and Plan for Biomass Technology in the United States

Industrial development was pushed by the US President [111] and by the US Congress [112], initially in 2000. In the USA it is intended that by 2020 at least 25 % of organic-carbon-based industrial feedstock chemicals and 10 % of liquid fuels (compared with levels in 1994) will be produced by biobased industry. This would mean that more than 90 % of the consumption of organic chemicals in the US and up to 50 % of liquid fuel needs would be biobased products [4].

The Biomass Technical Advisory Committee (BTAC) of the USA in which leading representatives of industrial companies, for example Dow Chemical, E.I. du Pont de Nemours, Cargill Dow LLC, and Genencor International, and Corn growers associations and the Natural Resources Defense Council are involved and which acts as advisor to the US government, has made a detailed plan with steps toward targets of 2030 with regard to bioenergy, biofuels, and bioproducts (Table 1) [113].

Simultaneously, the plan *Biomass Technology in the United States* has been published [114] in which research, development, and construction of biorefinery demonstration plants are determined. Research and development are necessary to:

1) increase scientific understanding of biomass resources and improve the tailoring of those resources;
2) improve sustainable systems to develop, harvest, and process biomass resources;
3) improve efficiency and performance in conversion and distribution processes and technologies for development of a host of biobased products and
4) create the regulatory and market environment necessary for increased development and use of biobased products.

The Biomass Advisory Committee has established specific research and development objectives for feedstock production research. Target crops should include oil and cellulose-producing crops that can provide optimum energy content and usable plant components. Currently, however, there is a lack of understanding of plant biochemistry and inadequate genomic and metabolic information about many potential crops. Specific research to produce enhanced enzymes and chemical catalysts could advance biotechnology capabilities.

3.4. Vision and Goals and Plan for Biomass Technology in the European Union and Germany

In Europe there are already regulations about substitution of nonrenewable resources by biomass in the field of biofuels for transportation [125] and the "Renewable energy law" of 2000 [126]. According to the EC Directive "On the promotion of the use of biofuels" the following products are regarded as "biofuels":

(a) "bioethanol", (b) "biodiesel", (c) "biogas", (d) "biomethanol", (e) "biodimethyl ether",

(f) "bio-ETBE (ethyl tertiary-butyl ether)" on the basis of bioethanol,

(g) "bio-MTBE (methyl tertiary butyl ether)" on the basis of biomethanol, and

(h) "synthetic biofuels", (i) "biohydrogen", (j) pure vegetable oil

Member States of the EU have been requested to define national guidelines for a minimum amounts of biofuels and other renewable fuels (with a reference value of 2 % by 2005 and 5.75 % by 2010 calculated on the basis of energy

Table 1. The US national vision goals for biomass technologies by the Biomass Technical Advisory Committee [113]

Year	2002	2010	2020	2030
BioPower (BioEnergy)Biomass share of electricity and heat demand in utilities and industry	2.8 % (2.7 quad)[a]	4 % (3.2 quad)	5 % (4.0 quad)	5 % (5.0 quad)
BioFuels Biomass share of demand for transportation fuels	0.5 % (0.15 quad)	4 % (1.3 quad)	10 % (4.0 quad)	20 % (9.5 quad)
BioProducts Share of target chemicals that are biobased	5 %	12 %	18 %	25 %

[a] 1 quad=1 quadrillion BTU=1 German billiarde BTU; BTU=British thermal unit; 1 BTU=0.252 kcal, 1 kW=3413 BTU, 1 kcal=4.186 kJ

content of all petrol and diesel fuels for transport purposes). Table 2 summarizes this goal of the EU and also those of Germany with regard to establishment of renewable energy and biofuel [127, 128].

Today there are no guidelines concerning "biobased products" in the European Union and in Germany. After passing directives relating to bioenergy and biofuels, however, such a decision is on the political agenda. The "biofuels" directive already includes ethanol, methanol, dimethyl ether, hydrogen, and biomass pyrolysis which are fundamental product lines of the future biobased chemical industry.

In the year 2003, an initiative group called "Biobased Industrial Products" consisting of members from industry, small and middle-class businesses, and research, and development facilities met and formulated a strategy paper, called "BioVision 2030" [129]. This strategy paper has been included in the resolution of the German Government (Deutscher Bundestag) on the topic "Accomplish basic conditions for the industrial utilization of renewable resources in Germany" [130]. An advisory committee consisting of members of the chemical industry, related organizations, research facilities, and universities has been established to generate a plan concerning the formulation of the objectives for the third column, bio-products in Europe (Table 2) [131].

A recent vision paper published by the Industrial Biotechnology Section of the European Technology platform for Sustainable Chemistry foresee up to 30 % of raw materials for chemical industry coming from renewable sources by 2025 [132]. Lately European Commission and U S Department of Energy are come to an agreement for cooperation on this field [133].

4. Principles of Biorefineries

4.1. Fundamentals

Biomass, similar to petroleum, has a complex composition. Its primary separation into main groups of substances is appropriate. Subsequent treatment and processing of those substances lead to a whole range of products. Petrochemistry is based on the principle of generating simple to handle and well defined chemically pure products from hydrocarbons in refineries. In efficient product lines, a system based on family trees has been built, in which basic chemicals, intermediate products, and sophisticated products are produced. This principle of petroleum refineries must be transferred to biorefineries. Biomass contains the synthesis performance of the nature and has different C:H:O:N ratio from petroleum. Biotechnological conversion will become, with chemical conversion, a big player in the future (Fig. 3).

Thus biomass can already be modified within the process of genesis in such a way that it is adapted to the purpose of subsequent processing, and particular target products have already been formed. For those products the term "precursors" is used. Plant biomass always consists of the basic products carbohydrates, lignin, proteins, and fats, and a variety of substances such as vitamins, dyes, flavors, aromatic essences of very different chemical structure. Biorefineries combine the essential technologies which convert biological raw materials into the industrial intermediates and final products (Fig. 4).

A technically feasible separation operation, which would enable separate use or subsequent processing of all these basic compounds, is currently in its initial stages only. Assuming that of

Table 2. Targets of the EU and Germany with regard to the introduction of technologies based on renewable resources

Year	2001	2005	2010	2020–2050
Bioenergy Share of wind power, photovoltaics, biomass and geothermal electricity and heat demand in utilities and industry	7.5 %	–	12.5 %	26 % (2030)58 % (2050)
Biofuels Biomass share of demand in transportation fuels (petrol and diesel fuels)	1.4 %	2.8 %	5.75 %	20 % (2020)
Biobased Products Share of target chemicals that are biobased	8 %			

Figure 3. Comparison of the basic-principles of the petroleum refinery and the biorefinery

the estimated annual production of biomass by biosynthesis of 170 billion tons 75 % is carbohydrates, mainly in the form of cellulose, starch, and saccharose, 20 % lignin, and only 5 % other natural compounds such as fats (oils), proteins, and other substances [134], the main attention should first be focused on efficient access to carbohydrates, and their subsequent conversion to chemical bulk products and corresponding final products. Glucose, accessible by microbial or chemical methods from starch, sugar, or cellulose, is, among other things, predestined for a key position as a basic chemical, because a broad range of biotechnological or chemical products is accessible from glucose [135]. For starch the advantage of enzymatic compared with chemical hydrolysis is already known [136].

For cellulose this is not yet realized. Cellulose-hydrolyzing enzymes can only act effectively after pretreatment to break up the very stable lignin/cellulose/hemicellulose composites [137]. These treatments are still mostly thermal, thermomechanical, or thermochemical, and require considerable input of energy. The arsenal for microbial conversion of substances from glucose is large, and the reactions are energetically profitable. It is necessary to combine degradation processes via glucose to bulk chemicals with the building processes to their subsequent products and materials (Fig. 5).

Among the variety of microbial and chemical products possibly accessible from glucose, lactic acid, ethanol, acetic acid, and levulinic acid, in particular, are favorable intermediates for generation of industrially relevant product family trees. Here, two potential strategies are considered: first, development of new, possibly biologically degradable products (follow-up products from lactic and levulinic acids) or, second, entry as intermediates into conventional product lines

Figure 4. Providing code-defined basic substances (via fractionation) for development of relevant industrial product family trees [81, 82]

(acrylic acid, 2,3-pentanedione) of petrochemical refineries [81].

4.2. Definition of the Term "Biorefinery"

The young working field "Biorefinery Systems" in combination with "Biobased Industrial Products" is, in various respects, still an open field of knowledge. This is also reflected in the search for an appropriate description. A selection is given below.

The term "Green Biorefinery" was been defined in the year 1997 as: "Green biorefineries represent complex (to fully integrated) systems

of sustainable, environmentally and resource-friendly technologies for the comprehensive (holistic) material and energetic utilization as well as exploitation of biological raw materials in form of green and residue biomass from a targeted sustainable regional land utilization" [76]. The original term used in Germany "complex construction and systems" was substituted by "fully integrated systems". The US Department of Energy (DOE) uses the following definition [138]: "A biorefinery is an overall concept of a processing plant where biomass feedstocks are converted and extracted into a spectrum of valuable products. Based on the petrol-chemical refinery." The American National Renewable Energy Laboratory (NREL) published the definition [139]: "A biorefinery is a facility that integrates biomass conversion processes and equipment to produce fuels, power, and chemicals from biomass. The biorefinery concept is analogous to today's petroleum refineries, which produce multiple fuels and products from petroleum. Industrial biorefineries have been identified as the most promising route to the creation of a new domestic biobased industry."

A general definition is: "Biorefining is the transfer of the efficiency and logic of fossil-based chemistry and substantial converting industry as well as energy production onto the biomass industry".

There is an agreement about the *objective*, which is briefly defined as: "Developed biorefineries, so called "phase III-biorefineries" or "generation III-biorefineries", start with a biomass–feedstock-mix to produce a multiplicity of most various products by a technologies-mix" [77] (Fig. 6).

An example of the type "generation-I biorefinery" is a dry milling ethanol plant. It uses grain as a feedstock, has a fixed processing capability, and produces a fixed amount of ethanol, feed co-products, and carbon dioxide. It has almost no flexibility in processing. Therefore, this type can be used for comparable purposes only.

An example of a type "generation-II biorefinery" is the current wet milling technology. This technology uses grain feedstock, yet has the capability to produce a variety of end products depending on product demand. Such products include starch, high-fructose corn syrup, ethanol, corn oil, plus corn gluten feed, and meal. This type opens numerous possibilities to connect industrial product lines with existing agricultural production units. "Generation-II biorefineries" are, furthermore, plants like NatureWorks PLA facility [1, 28] (see Sections 2 and 3.1) or ethanol biorefineries, for example Iogen's wheat straw to ethanol plant [147].

Third generation (generation-III) and more advanced biorefineries have not yet been built but will use agricultural or forest biomass to produce multiple products streams, for example ethanol for fuels, chemicals, and plastics [140, 147].

4.3. The Role of Biotechnology

The application of biotechnological methods will be highly important with the development of biorefineries for production of basic chemicals, intermediate chemicals, and polymers [141 – 143]. The integration of biotechnological methods must be managed intelligently in respect of physical and chemical conversion of the biomass. Therefore the biotechnology cannot remain limited to glucose from sugar plants and starch from starch-producing plants. One main objective is the economic use of biomass containing lignocellulose and provision of glucose in the family tree system. Glucose is a key chemical for microbial processes. The preparation of a large number of family tree-capable basic chemicals is shown in subsequent sections.

4.3.1. Guidelines of Fermentation Section within Glucose-product Family Tree

Among the variety of chemical products, and derivatives of these, accessible microbially from glucose a product family tree can be developed, for example (C-1)-chemicals methane, carbon dioxide, methanol; (C-2)-chemicals ethanol, acetic acid, acetaldehyde, ethylene, (C-3)-chemicals lactic acid, propanediol, propylene, propylene oxide, acetone, acrylic acid, (C-4)-chemicals diethyl ether, acetic acid anhydride, malic acid, vinyl acetate, *n*-butanol, crotonaldehyde, butadiene, 2,3-butanediol, (C-5)-chemicals itaconic acid, 2,3-pentane dione, ethyl lactate, (C-6)-chemicals sorbic acid, parasorbic acid, citric acid, aconitic acid, isoascorbinic

Figure 6. Basic principles of a biorefinery (generation III biorefinery) [81]

Figure 7. Biotechnological sugar-based product family tree

acid, kojic acid, maltol, dilactide, (C-8)-chemicals 2-ethyl hexanol (Fig. 7).

Guidelines are currently being developed for the fermentation section of a biorefinery. The question of efficient arrangement of the technological design for production of bulk chemicals needs an answer. Considering the manufacture of lactic acid and ethanol, the basic technological operations are very similar. Selection of biotechnologically based products from biore-

fineries should be done in a way such that they can be produced from the substrates glucose or pentoses. Furthermore the fermentation products should be extracellular. Fermenters should have batch, feed batch, or CSTR design. Preliminary product recovery should require steps like filtration, distillation, or extraction. Final product recovery and purification steps should possibly be product-unique. In addition, biochemical and chemical processing steps should be advantageously connected.

Unresolved questions for the fermentation facility include:

1) whether or not the entire fermentation facility can/should be able to change from one product to another;
2) whether multiple products can be run in parallel, with shared use of common unit operations;
3) how to manage scheduling of unit operations; and
4) how to minimize in-plant inventories, while accommodating necessary change-over between different products in the same piece of equipment [98].

4.4. Building Blocks, Chemicals and Potential Screening

A team from Pacific Northwest National Laboratory (PNNL) and NREL submitted a list of twelve potential biobased chemicals [101]. A key area of the investigation as biomass precursors, platforms, building blocks, secondary chemicals, intermediates, products and uses (Fig. 8).

The final selection of 12 building blocks began with a list of more than 300 candidates. A shorter list of 30 potential candidates was selected by using an iterative review process based on the petrochemical model of building blocks, chemical data, known market data, properties, performance of the potential candidates, and previous industry experience of the team at PNNL and NREL. This list of 30 was ultimately reduced to 12 by examining the potential markets for the building blocks and their derivatives and the technical complexity of the synthetic pathways.

The reported block chemicals can be produced from sugar by biological and chemical conversions. The building blocks can be subsequently converted to several high-value biobased chemicals or materials. Building-block chemicals, as considered for this analysis, are molecules with multiple functional groups with the potential to be transformed into new families of useful molecules. The twelve sugar-based building blocks are 1,4-diacids (succinic, fumaric, and malic), 2,5-furandicarboxylic acid, 3-hydroxypropionic acid, aspartic acid, glucaric acid, glutamic acid, itaconic acid, levulinic acid, 3-hydroxybutyrolactone, glycerol, sorbitol, and xylitol/arabinitol [101].

A second-tier group of building blocks was also identified as viable candidates. These include gluconic acid, lactic acid, malonic acid, propionic acid, the triacids citric and aconitic, xylonic acid, acetoin, furfural, levuglucosan, lysine, serine, and threonine. Recommendations for moving forward include:

- examining top value products from biomass components, for example aromatic compounds, polysaccharides, and oils;
- evaluating technical challenges in more detail in relation to chemical and biological conversion; and
- increasing the suites of potential pathways to these candidates.

The co-production of organic acids, ethanol, and electricity, as well as the opportunities for their integration, will improve overall economics. [132]. Also, the possibilities of catalysis for the production of platform chemicals have not yet sufficiently been exploited [144]. In addition, further investigations on microbial biology and bioprocessing are anticipated [145].

No further down select products from syngas was undertaken. For the purposes of the study from PNNL and NREL hydrogen and methanol comprise the best short-term prospects for biobased commodity chemical production, because obtaining simple alcohols, aldehydes, mixed alcohols, and Fischer-Tropsch liquids from biomass is not economically viable and requires additional development [101].

Figure 8. Model of a biobased product flow-chart for biomass feedstock [101]

5. Biorefinery Systems and Design

5.1. Introduction

Biobased products are prepared for a usable economic use by meaningful combination of different methods and processes (physical, chemical, biological, and thermal). It is therefore necessary that basic biorefinery technologies are developed. For this reason profound interdisciplinary cooperation of various disciplines in research and development is inevitable. It seems reasonable, therefore, to refer to the term "biorefinery design", which means: "bringing together well founded scientific and technological basics, with similar technologies, products, and product lines, inside biorefineries". The basic conversions of each biorefinery can be summarized as follows. In the first step, the precursor-containing biomass is separated by physical methods. The main products (M_1–M_n) and the by-products (B_1–B_n) will subsequently be subjected to microbiological or chemical methods. The follow-up products (F_1–F_n) of the main and by-products can also be converted or enter the conventional refinery (Fig. 6).

Currently four complex biorefinery systems are used in research and development:

1) the "lignocellulosic feedstock biorefinery" which use "nature-dry" raw material, for example cellulose-containing biomass and waste;
2) the "whole crop biorefinery" which uses raw material such as cereals or maize;
3) the "green biorefineries" which use "nature-wet" biomass such as green grass, alfalfa, clover, or immature cereal [81, 82]; and
4) the "biorefinery two platforms concept" includes the sugar platform and the syngas platform [101].

5.2. Lignocellulosic Feedstock Biorefinery

Among the potential large-scale industrial biorefineries the lignocellulose feedstock (LCF) biorefinery will most probably be pushed through with the greatest success. On the one side the raw material situation is optimum (straw, reed, grass, wood, paper-waste, etc.), on the other side conversion products have a good position on both the traditional petrochemical and future biobased product market [146, 148, 149]. An important point for utilization of biomass as chemical raw material is the cost of raw material. Currently the cost of corn stover or straw is 30 US$/ton and that of corn is 110 US$/ton (3 US$/ bushel; US bushel corn =25.4012 kg=56 lb) [150].

Lignocellulose materials consist of three primary chemical fractions or precursors:

- hemicellulose/polyoses, sugar polymers of, predominantly, pentoses;
- cellulose, a glucose polymer; and
- lignin, a polymer of phenols (Fig. 9).

$$\text{Lignocellulose} + H_2O \rightarrow \text{Lignin} + \text{Cellulose} + \text{Hemicellulose}$$
$$\text{Hemicellulose} + H_2O \rightarrow \text{Xylose}$$
$$\text{Xylose } (C_5H_{10}O_5) + \text{acid Catalyst} \rightarrow \text{Furfural } (C_5H_4O_2) + 3H_2O$$
$$\text{Cellulose}(C_6H_{10}O_5) + H_2O \rightarrow \text{Glucose } (C_6H_{12}O_6)$$

Figure 9. A possible general equation for conversion at the LCF biorefinery

The lignocellulosic biorefinery-regime is distinctly suitable for genealogical compound trees. The main advantages of this method is that the natural structures and structural elements are preserved, the raw materials are inexpensive, and large product varieties are possible (Fig. 10). Nevertheless there is still a demand for development and optimization of these technologies, e.g., in the field of separation of cellulose, hemicellulose and lignin, and utilization of the lignin in the chemical industry.

An overview of potential products of an LCF biorefinery is shown in Figure 11. In particular furfural and hydroxymethylfurfural are interesting products. Furfural is a starting material for production of nylon 6,6 and nylon 6. The original process for production of nylon-6,6 was based on furfural (see also 2.2). The last of these production plants was closed in 1961 in the USA, for economic reasons (the artificially low price of petroleum). Nevertheless the market for nylon 6 is huge. Catalytic transformation of these future feedstocks provides new market opportunities. Levulinic acid is one of 12 bioderived feedstocks and it can be obtained directly by cellulose hydrolysis [101]. A number of high value derivatives, such as pyrrolidones, monomers for the synthesis of high Tg amorphous polymers and fuel additives, such as ethyl levulinate can be prepared [123, 151].

There are, however, still some unsatisfactory aspects of the LCF, for example the utilization of lignin as fuel, adhesive, or binder. Unsatisfactory because the lignin scaffold contains substantial amounts of mono-aromatic hydrocarbons, which, if isolated in an economically efficient way, could add a significant increase in value to the primary processes. It should be noticed there are no natural enzymes capable of splitting the naturally formed lignin into basic monomers as easily as is possible for natural polymeric carbohydrates or proteins [152].

An attractive process accompanying the biomass-nylon-process is the already mentioned hydrolysis of the cellulose to glucose and the production of ethanol. Some yeasts cause disproportionation of the glucose molecule during their generation of ethanol from glucose, which shifts almost all its metabolism into ethanol production, making the compound obtainable in 90 % yield (w/w; with regard to the chemical equation for the process).

On the basis of recent technology a plant has been conceived for production of the main products furfural and ethanol from LC feedstock from West Central Missouri (USA). Optimal

Figure 10. Lignocellulosic feedstock biorefinery

Figure 11. Products of a lignocellulosic feedstock biorefinery (LCF-biorefinery, Phase III) [81, 82, 98]

profitability can be achieved with a daily consumption of approximately 4360 tons of feedstock. The plant produces 47.5 million gallon of ethanol and 323 tons of furfural annually [77].

Ethanol can be used as a fuel additive. It is also a connecting product to the petrochemical refinery, because it can be converted into ethene by chemical methods and it is well-known that ethene is at the start of a series of large-scale technical chemical syntheses for production of important commodities such as polyethylene or poly(vinyl acetate). Other petrochemically produced substances, for example hydrogen, methane, propanol, acetone, butanol, butandiol, itaconic acid, and succinic acid, can also be manufactured by microbial conversion of glucose [153, 154].

5.3. Whole-crop Biorefinery

Raw materials for the "whole crop biorefinery" are cereals such as rye, wheat, triticale, and maize. The first step is mechanical separation into corn and straw, approximately in a 1:1.1–1.3 ratio, respectively, see Fig. 12 [155]. Straw is a mixture of chaff, nodes, ears, and leaves. The straw is an LC feedstock and may further be processed in a LCF biorefinery.

There is the possibility of separation into cellulose, hemicellulose, and lignin and their further conversion in separate product lines which are shown in the LCF biorefinery. The straw is also a starting material for production of syngas by pyrolysis technology. Syngas is the basic material for synthesis of fuels and methanol (Fig. 13).

The corn may either be converted into starch or used directly after grinding to meal. Improved molecular disassembly and depolymerization of grain starch to glucose are key to reducing energy use in the bioconversion of glucose to chemicals, ingredients, and fuels. [156, 157]

Further processing may be conducted by four processes — breaking up, plasticization, chemical modification, or biotechnological conversion via glucose. The meal can be treated and finished by extrusion into binder, adhesives, and filler. Starch can be finished by plasticization (co- and mix-polymerization, compounding with other polymers), chemical modification (etherification into carboxymethyl starch; esterification and re-esterification into fatty acid esters via acetic starch; splitting reductive amination into ethylenediamine, etc., hydrogenative splitting into sorbitol, ethylene glycol, propylene glycol, and glycerin), and biotechnological

Figure 12. Whole-crop biorefinery based on dry milling

Figure 13. Products from a whole-crop biorefinery [81, 82]

conversion into poly-3-hydroxybutyric acid [72, 79, 95, 96, 158, 159]

An alternative to traditional dry fractionation of mature cereals into grains and straw only was been developed by Kockums Construction (Sweden), which later became Scandinavian Farming. In this crop-harvest system whole immature cereal plants are harvested. The whole harvested biomass is conserved or dried for long-term storage. When convenient, it can be processed and fractionated into kernels, straw chips of internodes, and straw meal (leaves, ears, chaff, and nodes) (see also 5.4).

Fractions are suitable as raw materials for the starch polymer industry, the feed industry, the cellulose industry, and particle board producers, gluten can be used by the chemical industry and as a solid fuel. Such dry fractionation of the whole crop to optimize the utilization of all botanical components of the biomass has been described [160, 161]. A biorefinery and its profitability has been described elsewhere [162].

Figure 14. Whole-crop biorefinery, wet-milling

One expansion of the product lines in grain processing is the "whole crop wet mill-based biorefinery". The grain is swelled and the grain germ is pressed, releasing high-value oils. The advantages of whole-crop biorefinery based on wet milling are that production of natural structures and structure elements such as starch, cellulose, oil, and amino acids (proteins) are kept high yet well known basic technology and processing lines can still be used. High raw material costs and, for industrial utilization, the necessary costly source technology are the disadvantages. Some of the products formed command high prices in, e.g., the pharmaceutical and cosmetics industries (Figs. 14 and 15). The basic biorefinery technology of corn wet mills used 11 % of the US corn harvest in 1992, made products worth $7.0 billion, and employed almost 10,000 people [4].

Wet milling of corn yields corn oil, corn fiber, and corn starch. The starch products of the US corn wet milling industry are fuel alcohol (31 %), high-fructose corn syrup (36 %), starch (16 %), and dextrose (17 %). Corn wet milling also generates other products (e.g. gluten meal, gluten feed, oil) [65]. An overview about the product range is shown in Figure 15.

5.4. Green Biorefinery

Green biorefineries are also multi-product systems and furnish cuts, fractions, and products in accordance with the physiology of the corresponding plant material, which maintains and utilizes the diversity of syntheses achieved by nature. Most green biomass is green crops, for example grass from cultivation of permanent grass land, closure fields, nature reserves, or green crops, such as lucerne, clover, and immature cereals from extensive land cultivation. Green crops are a natural chemical factory and food plant and are primarily used as forage and as a source of leafy vegetables. A process called wet-fractionation of green biomass, green crop fractionation, can be used for simultaneous manufacture of both food and non food items [163].

Scientists in several countries, in Europe and elsewhere, have developed green crop fractionation [164 – 166]. Green crop fractionation is now studied in approximately 80 countries [167]. Several hundred temperate and tropical plant species have been investigated for green crop fractionation [166, 168, 169] and more than 300,000 higher plants species have still to be investigated. The subject has been covered by several reviews [76, 164 – 166, 169 – 173]. Green biorefineries can, by fractionation of green plants, process from a few tonnes of green crops per hour (farm scale process) to more than 100 tonnes per hour (industrial scale commercial process).

Careful wet fractionation technology is used as a first step (primary refinery) to isolate the contents of the green crop (or humid organic waste goods) in their natural form. Thus, they are separated into a fiber-rich press cake (PC) and a nutrient-rich green juice (GJ).

Figure 15. Products from a whole-crop wet mill-based biorefinery

The advantages of the green biorefinery are high biomass profit per hectare, good coupling with agricultural production, and low price of the raw materials. Simple technology can be used and there is good biotechnical and chemical potential for further conversion (Fig. 16). Rapid primary processing or use of preservation methods, for example silage production or drying, are necessary, both for the raw materials and the primary products, although each method of preservation changes the content of the materials.

In addition to cellulose and starch, the press cake contains valuable dyes and pigments, crude drugs and other organic compounds. The green juice contains proteins, free amino acids, organic acids, dyes, enzymes, hormones, other organic substances, and minerals. Application of the methods of biotechnology results in conversion, because the plant water can simultaneously be used for further treatment. In addition, the lignin–cellulose composite is not as intractable as lignocellulose-feedstock materials. Starting from green juice the main focus is directed toward products such as lactic acid and its derivatives, amino acids, ethanol, and proteins. The press cake can be used for production of green feed pellets, as raw material for production of chemicals, for example levulinic acid, and for conversion to syngas and hydrocarbons (synthetic biofuels). The residues of substantial conversion are suitable for production of biogas combined with generation of heat and electricity (Fig. 17). Reviews have been published on the concepts, contents, and goals of the green biorefinery [76, 78, 124, 146].

5.5. Two-platform Concept and Syngas

The "two-platform concept" is one which uses biomass consisting, on average, of 75 % carbohydrates which can be standardized as a "intermediate sugar platform", as a basis for further conversion, but which can also be converted thermochemically into synthesis gas and the products made from this. The "sugar platform" is based on biochemical conversion processes and focuses on fermentation of sugars extracted from biomass feedstocks. The "syngas platform" is based on thermochemical conversion processes and focuses on the gasification of biomass feedstocks and by-products from conversion processes [66, 101, 139]. In addition to the gasification other thermal and thermochemi-

Figure 16. A "green biorefinery" system

Figure 17. Products from the green biorefinery. In this illustration a green biorefinery has been combined with a green crop-drying plant [81, 82]

cal biomass conversion methods have also been described — hydrothermolysis, pyrolysis, thermolysis, and burning. The application chosen depends on the water content of biomass [174].

The gasification and other thermochemical conversions concentrate on utilization of the precursor carbohydrates and their intrinsic carbon and hydrogen content. The proteins, lignin, oils and lipids, amino acids, and other nitrogen and sulfur-containing compounds occurring in all biomass are not taken into account (Fig. 18).

The advantage of this concept is that the production of energy, fuels, and biobased products is possible using only slightly complex and low-tech technology, for example saccharification and syngas technology [3]. The sugar platform also enables access to a huge range of family-tree-capable chemicals (Figs. 7 and 8).

In-situ conversion of biomass feedstock into liquid or gas could be one way of using existing infrastructure (developed pipe network), but with the disadvantages of the need to remove

Figure 18. The sugar platform and the syngas platform [139]

hetero-atoms (O, N, S) and minerals present in the biomass and the highly endothermic nature of the syngas process [175]. Currently, production of simple alcohols, aldehydes, mixed alcohols, and Fischer-Tropsch liquids from biomass is not economically viable and additional developments are required [101] (Fig. 19).

Recent research approaches for the production of liquid fuels are aqueous-phase catalytic processes for the conversion of biobased building blocks into H and C1–C15 alkanes [176].

6. Biorefinery Economy

Industrial utilization of raw materials from agriculture, forestry, landscape conservation, and organic waste management for large-scale converting industry and chemical industry as well for producing energy is still in its beginnings. The concept of a biorefinery is analogous to a petroleum refinery where a feedstock, crude oil, is converted to fuels, chemical products, and energy. In the case of a biorefinery, plant biomass is used as a feedstock to produce a diverse set of products for all areas of life, such as fuels, chemicals, polymers, lubricants, adhesives, fertilizer, and energy [132, 133, 177].

Although similar to oil refineries, biorefineries exhibit some important differences. First, biorefineries can utilize a variety of feedstocks. Consequently, they require the development of a larger range of processing technologies and biorefinery systems to deal with compositional differences in the feedstock. Second, the biomass feedstock is bulkier (has a lower energy density) than fossil fuels. Therefore, economics dictate decentralized biorefineries closer to feedstock sources. Conversion of lignocellulosic feedstock to the main products ethanol and furfural has been conceived with optimal profitability (see 5.2, [77]).

The economics of biorefineries are dependent on the production of co-products, such as protein, chemicals, polymers, and power, to provide revenue streams that offset processing costs. Generation of co-products also results in more efficient utilization of biomass and land along with more effective use of invested capital [178, 179]. Generally, because of low cost, plentiful supply, and amenability to biotechnology, carbohydrates appear likely to be the dominant source of feedstock for biocommodity processing [180].

Biorefineries have the potential to reduce sugar costs from about 8–9 cents per pound in the USA today (ca. 2006) to about 4 cents per pound in three to four years, and even lower as the biorefineries become more integrated. It is even possible to foresee a case in which the net cost of producing sugar in an integrated biorefinery is zero, because byproducts such as lignin and proteins generate the value [181].

Plants like NatureWorks PLA are Generation-II biorefineries (see 5.5 [1, 28, 182]). Polylactic acid (PLA) is current produced by using corn as feedstock. The corn-based sugar raw material can account for approximately 25–40 % of the total cost of PLA. Today PLA made from corn is competitive with traditional

Figure 19. Syngas-based product family tree [175, 190]

petrochemical-based polymers, given its combination of performance in applications, costs, and environmental benefits. Lignocellulose biorefineries are important to PLA because of the improvements in both the cost of the raw material and the overall environmental footprint [1].

In a lignocellulosic biorefinery in which multiple value-added co-products are produced and the lignin is used for energy, the cost of PLA would be lower, primarily because of the lower cost of sugars. In this case the cost of sugar raw materials could be as low as 15–25 % of the total cost of PLA production. Importantly, the environmental footprint would improve because of the replacement of petrochemical-based energy by lignin-based renewable energy to drive the manufacturing process. PLA made by a lignocellulosic biorefinery in the future will have competitive advantages.

Biorefineries utilizing lignocellulosic feedstocks hold the promise of lower net feedstock

Figure 20. Exemplary calculation on the use of straw for the production of ethanol for fuels and basic chemicals in Germany

costs combined with an improved environmental footprint. PLA already has an advantage over some traditional petrochemical-based polymers such as poly(ethylene terephthalate), PET. Improvements in cost will make it competitive with polypropylene and polystyrene, too.

Recently (ca. 2006), the goal of the U.S. Department of Agriculture and the U.S. Department of Energy is the additional supply of 10^9 tons of biomass at a price of 35 $ per ton (dry matter) per year for industrial chemical and biotechnological utilization, without the restriction of today's applications of biomass from agriculture and forestry [183]. Annually in the USA, 400×10^6 tons of straw (dry matter) has been produced but not used [146, 184].

Example of Use of Straw for Chemicals and Fuels in Germany. Germany produces on average 50×10^6 t/a (dry matter) of cereal grains. The ratio of grain to straw (chaff, nodes, ears, leaves) is approx. 1:1.3 [155].

That means that approximately 50×10^6 t (dry matter) of straw can be used for industry without reducing today's use in organic fertilizing and natural field cultivation. Furthermore, a life-cycle analysis has shown that the use of straw for a lignocellulosic biorefinery is more ecologically advantageous than other possible applications (field cultivation, production of liquid fuels via Fischer–Tropsch, or energy production) [185].

An exemplary calculation for using of this straw for industry (basic chemicals) and fuels (ethanol production) is shown in Figure 20.

The generated ethanol could cover both the demand for ethylene (fossil-based production in Germany: 5×10^6 t) and for E10 fuels (German consumption of gasoline/Otto petrol: 25×10^6 t).The residual ethanol could be applied as a chemical or for E85 fuel (Fig. 20).

7. Outlook and Perspectives

Biorefineries are production plants in which biomass is economically and ecologically converted to chemicals, materials, fuels, and energy. For successful development of "industrial biorefinery technologies" and "biobased products" several problems must be solved. It will be necessary to increase the production of substances (cellulose [186], starch, sugar [187], oil) from basic biogenic raw materials and to promote

the introduction and establishment of biorefinery demonstration plants [188, 189]. Ecological transport of biomass must also be developed, for example, utilization of already developed pipelines.

Another important aspect is committing chemists, biotechnologists, and engineers to the concept of biobased products and biorefinery systems and promoting the combined biotechnological and chemical conversion of substances. Last, but not least, the development of systematic approaches to new syntheses and technologies is required to meet the sustainable principles of "ideal synthesis" and "principles of green chemistry and process engineering" [191 – 193].

The biobased economy and its associated biorefineries will be shaped by many of the same forces that shaped the development of the hydrocarbon economy and its refineries over the past century [182, 194].

Many of the biorefinery elements required for financial success seem to be currently present, for example, high-volume, low-cost applications (ethanol, lactic acid), multiple alternative product streams, ability to shift to different products quickly when required [195], and acceptable cost structure for biomass.

Several financial requirements will enable the biorefinery concept to become a reality in the near future:

- Parts of the overall biorefinery scheme that can operate in a stand-alone manner from a financial perspective, and the ability to evolve from there
- The potential for multiproduct or co-product streams, which may ultimately drive efforts to engineer crops to maximize their potential
- The ability to make use of a variety of feedstocks as hedging strategy and the advantage of pricing opportunities:
- Manageable capital requirements and favorable investment environment
- Government enablement (funding demonstration/development pilot plants, reasonable regulation of biorefinery operations, favorable taxation, strategic market support to give new biorefinery products a head start [196].

1. Introduction

Food products based on cereal grains belong to the staple foods all over the world. In 2004/2005 2000×10^6 t of cereal grains were harvested [1]. Millions of tons of cereal grains are processed in the plants of the food industry day by day. The most important intermediate product is flour. Grain flour or coarser fractions of the kernels are further processed. One possible process technology is extrusion.

There are many kinds of food products which are produced by extrusion technology such as pasta, breakfast cereals, cereal flakes, baby food, bread crumbs, or binders for, e.g., sauces or soups. In Chapter 2 a short overview on food extrusion technology is given. In the following chapters cereal products are discussed which are produced with the help of extrusion technology. The Chapter 3 describes pasta and the pasta production technology. A description of the extrusion process for the production of modified flour as food ingredients is found in Chapter 4. The Chapter 5 gives an overview over breakfast cereals and their possible production methods. The last chapter 6 is devoted to reconstituted and fortified rice kernels.

2. Food Extrusion Technology

Extruders have been used in a large variety and increasing number of food applications. Nearly all of these involve mixing of food ingredients with water to achieve hydration. In most cases, a number of ingredients are involved to make a finished extruded food product. Food ingredients are composed of starches, proteins, fiber, fat, minerals, vitamins and water. Major raw materials are cereal grains, or flours of those, respectively.

Extrusion is generally defined as a process of forcing material through a defined opening. For this to occur, the material must be either completely or partly in a fluid form so that it does not block the opening when operating under reasonable pressure conditions.

In reality, extrusion systems provide other functions including solid conveying, melting, mixing, and metering. In the process the material may undergo chemical as well as physical changes.

In the food industry, single-screw extruders were first used in the pasta industry in the early 1930s. Cooking extruders were introduced in the 1940s to produce expanded corn snacks. Long single-screw cooking extruders were developed in the 1950s for production of pet food and expanded breakfast cereals. Twin-screw corotating cooking extruders were introduced in the late 1970s.

Food extruders have been divided into two general application categories.

For *forming applications*, low-shear single-screw extruders are basically used to form pellets with a minimum energy input to the product. The product applications include pasta, cold formed snacks, and unexpanded, precooked pellets. The screws have a deep channel (height/diameter, i.e., $H/D \approx 4$) with probably no compression and are running at low screw speed (below 50 rpm).

Cooking extrusion applications normally utilize medium- and high-shear single- and twin-screw extruders. In these, significant energy input to the product is provided by viscous heat dissipation with or without heat transfer through the barrel. Their screws run at higher speeds (100–500 rpm) with shallower channel depth and compression ratio up to 5:1 for single-screw extruders. Cooking extruders are used for cooking and forming of expanded or unexpanded products.

3. Pasta

3.1. Definition

The word "pasta" means "dough" in Italian. Its typical ingredients are wheat flour or semolina and water. Alternatives are potato flour (for gnocchi) and maize (corn) or rice flour (gluten-free products). It is also possible to add eggs, natural colorants such as spinach, tomatoes, or vitamins for certain products in the USA. The Italian type of pasta production uses only durum semolina and water. From the point of view of composition, pasta is a very simple food.

3.2. Market for Pasta

Today, a market for "Italian-style" pasta exists worldwide. It is not surprising that of all countries Italy has the higher per capita consumption of pasta. However, as shown in Table 1 in various other countries also high amounts of pasta are consumed.

Table 1. Pasta consumption of different countries [2]

Country	kg pasta per capita and year 2005
Italy	28.0
Venezuela	12.6
Tunisia	11.7
Switzerland	9.8
Greece	9.6
Sweden	9.0
USA	9.0
Peru	8.5
Germany	6.8
UK	2.5
Japan	1.7

As a general rule, pasta consumption has increased strongly since the 1970s. In Italy, on the other hand, consumption has tended to decline somewhat over the past 30 years. Surveys show pasta to be considered as a healthy product that is easy to store and quick to prepare. Besides the US pasta producers, the Italians are also benefiting from the higher pasta consumption in the USA due to the quantities imported from Italy. In the UK, market growth has slowed down to

an annual rate of about 2 % in 2001. The market for fresh pasta is much smaller, but is growing at about 10 % annually.

3.3. Production

The processing of grain into ready-to-consume pasta products involves numerous individual operations. The following chapters are discussing each step from raw material up to storage of dried pasta.

3.3.1. Raw Materials

3.3.1.1. Semolina

Semolina made from durum or hard wheat (for a definition, see → Bread and Other Baked Products, Chap. 2) must be of high quality and have a protein content of at least 12 %. The ash content will not affect the cooking quality of the pasta to any decisive extent. Rather, high ash content implies elevated protein content, which is of advantage for the cooking properties. However, higher ash values will affect the color of the pasta, which may become discolored to the point of becoming dark brown. Crude fibers and specks show up as dark inclusions in the end products and indicate inadequate cleaning in the grinding system. The color of the semolina should be amber.

It is an advantage if the semolina particles have the most narrow particle size distribution possible, that does not exceed 0.350 mm. Fine particles absorb water more readily than coarse particles, owing to their larger specific surface area. Therefore, the more homogeneous the particle size, the more uniform their wetting. This results in a better dough, shorter mixing times and thereby smaller mixers. This was extensively demonstrated by Manser [3] and Baltensberger [4]. The mixing times as a function of the particle size are specified in Table 2.

Table 2. Mixing time as function of particle size of semolina

630–125 µm	15 min mixing time
525–125 µm	15 min
525–0 µm	15 min
350–125 µm	10 min
250–0 µm	5 min

Table 2 shows clearly that the better water absorption by fine semolina (<350 µm) enables the mixing time to be reduced.

3.3.1.2. Water and Additive Addition

The water must have a clear appearance and be neutral in terms of odors and taste. It should contain a minimum amount of minerals and must always be of drinking water grade. Foreign substances and the microbial count are typically subject to limits. The feed water temperature must be adjusted to the semolina temperature in order to obtain a certain dough temperature. The water temperature should not exceed 50°C in order to prevent protein damage. During production, a uniform water temperature must be ensured.

Since also the egg content must be guaranteed when eggs are added to the pasta, legal regulations must be observed depending on the specific country of production. The egg quantity will typically vary between one and seven eggs per kilogram of semolina. Here, too, special attention must be paid to the bacteriological criteria. High priority must be given to special processing and the use of pasteurized egg products, because this raw material is highly perishable.

To color pasta, other additives such as tomatoes or spinach can be added. They can be included in the form of powders or liquids.

3.3.2. Material Handling

The raw materials supplied from the mill (semolina, flour) are stored in bins. From there, they are fed to the extrusion press for processing. The storage system also includes equipment for regrinding material obtained during cutting of the long goods (regrind). This regrind is filled through a manual intake hopper into the regrind bin. It is first ground and then added at low rates to the semolina. As this material has been processed before it is very compact. Regrind should not be added to long goods products, if possible, and to short goods only at low ratios up to maximum 10 %. The particle size of the regrind should not exceed 0.300 mm.

If egg pasta is to be produced, an egg conditioning and feed system must be provided.

Preferably, it should be installed in a separate section of the building and be kept absolutely clean.

3.3.3. Short Goods, Long Goods, and Process Technology

Some 250 different pasta product shapes are available in the market. Pasta is classified into four main product types: short goods, long goods, nidi, and twisted goods.

Short Goods. Short goods such as elbows, spirals, noodles, etc., are extruded through a circular die and cut to the desired length by a rotary knife as they leave the die. The products first pass through a shaking predrier in order to obtain superficial drying. This is needed to prevent them from sticking together and to stabilize their shape. As a predrier, a belt-type or drum-type unit can be used, depending on the shape produced. The advantage of the drum drier is that it continuously reshuffles the product. Piled on metal decks, the short goods pass through the belt drier in about 3 or 4 h. The completely dried products can be stored in bulk storage bins or belt stackers, depending on their particular shape. Short goods lines can also be applied for making cut-out and soup pasta. Soup pasta is dried to a final moisture of 6 %. Another possibility is to produce instant pasta using an additional belt steamer ahead of the drying process.

Long Goods. Long goods such as spaghetti, macaroni, etc., are extruded through a rectangular, long die. The extruded strands are automatically spread on sticks and cut to the same length. The loaded sticks pass through the drier (approx. 5 to 6 h) and are held in intermediate storage in a stacker before packaging. For packaging, the dried product is stripped from the sticks and cut to the desired length. In certain cases, the product is cut right after drying/cooling and placed in intermediate storage in a belt stacker.

Nidi and Twisted Goods. Nidi (nests of long good pasta) or twisted goods are extruded through a rectangular, long die. The extruded strands are automatically shaped into nidi or twisted forms and deposited on frames, which then pass through the drying line. After drying, the product slides from the frames and can be storage in a belt stacker.

Process Technology. The extrusion press is the first element in a series of machines that are needed for the actual production of pasta. In the extrusion press, the various raw materials are blended, mixed into homogeneous dough and kneaded. The dough is extruded into the various product shapes and cut to length. Besides the traditional pasta extrusion press, Bühler has developed the Polymatik extrusion technology (see Fig. 1) [5], an enclosed system which has allowed the process time to be substantially reduced compared with the traditional extrusion process. The dough preparation time, for example, was shortened from the original rough 15 min, that a traditional extrusion press require,s to about 20 s. The Polymatik system also offers crucial benefits in terms of hygiene and flexibility for product change.

Figure 1. Polymatik extrusion press from Bühler [5]

The Polymatik press is made up of three parts: mixer/kneader, press section and head section. The mixer/kneader consists of two corotating screws, with specific kneading elements additionally supporting dough production.

Inside the mixer/kneader and the extrusion barrel shear and thrust forces act upon the dough, kneading and compressing it. An optimized kneading process in which time plays a very important part is crucial for creating the gluten framework. The conveying action of the screw inside the extrusion barrel creates the pressure needed for shaping the various products. This pressure is between 95 and 120 bar. The heat generated by dough working inside the mixer/kneader and the extrusion press is dissipated through a barrel- and head-cooling system. The dough temperature throughout the extrusion

process should not exceed 50°C. Otherwise the gluten network would be damaged, which deteriorates the cooking characteristics of the finished pasta.

In practice, attempts are often made to intensify kneading of the dough in order to offset an irregular particle size and therefore the irregular water absorption of the product in order to prevent white specks in the finished product. But the resulting high heating of the dough will at least partially destroy the protein framework, degrading the cooking characteristics of the end product.

Air entrapped inside the pasta will affect the drying process and the appearance of the end product. Therefore, the air in the dough is evacuated in the extrusion zone using a vacuum system.

In the extrusion press head, the dough is spread across the entire face of the die. The dough is then extruded under high pressure into the desired shapes through the holes of this die. For cut-out goods, a dough belt is extruded which is calibrated and then transferred to a special cut-out machine. There, specialty products such as bowties are cut out of the belt, folded and fed to the drying line.

3.3.4. Drying

As mentioned above, drying may take place in different temperature ranges. A high-temperature phase during the drying process will reduce the drying times. This, in turn, results in smaller drying lines or higher production capacities for a given space. In addition, the high temperatures guarantee the microbiological safety of the products. However, the greatest benefit of higher drying temperatures is the improved product quality. The influence of the high-temperature phase strengthens the protein framework of the product. This produces a higher cooking tolerance, lower or complete absence of surface sliminess and better chewing characteristics ("al dente") of the end product. The influence of a high-temperature phase on the product characteristics was investigated in detail in [6]. It was found that the application of high drying temperatures together with a low product moisture (<15 %) will produce the most effective results. However, these investigations were conducted on a laboratory scale. In addition, high-temperature drying improves the product quality when lower-cost soft wheat flours are added, which tend to have a weak protein framework. But it should be noted that it is impossible to use this drying process to make high-quality products from low-quality raw materials.

Whereas conventional high-temperature drying uses temperatures up to about 75°C, in the Bühler drying process "Turbothermatik" temperatures in excess of 80°C are applied.

A typical drying diagram for long goods as applied today is shown in Figure 2. It must be noted, however, that the values specified are merely approximate, since the optimal drying curve has to be determined first for every single product, varying with the shape, raw materials, line design, etc.

Figure 2. Example of drying diagram for long goods [7]

To enable optimal control of the drying process, the drier is of modular design and is divided into zones allowing individual climate control (Fig. 3). In zones A1 to A4/A5, predrying takes place. B1 is the main drying zone, and C1 the stabilization zone. In C2, moisture is added to the product, and in D1 and D2 the product is cooled to ambient temperature. Each of these zones is equipped with a climate probe that measures the temperature and humidity of the drying air and transmits these values to the control system. The system then controls the heating valve and the fresh and exhaust air system of the drier to ensure a consistent climate. At the start and end of production, it is possible to inject steam in order to obtain the required air humidity. This required humidity is then achieved through the

Figure 3. Schematic representation of the C-line long-goods drier

product moisture released when the drier is fully loaded.

In the case of long goods, for example, the product is dried in the predrying zone within a very short time from approximately 30 % to about 16 % product moisture. The process parameters must be adjusted as a function of the raw material quality. The settings must be selected such that no crusting of the product is created. Otherwise, it will not be possible for the moisture remaining inside the product to be adequately released. For thermodynamic reasons, this entrapped moisture will create stresses in the product, which may lead to product breakage during storage. During the main drying time, the product is ideally dried to a final moisture content of about 12 to 12.5 %.

The longest drying phase in terms of time is the stabilization phase. It takes place at about 2 to 4°C lower temperatures than the high-temperature phase (main drying). The main purpose of stabilization is to relieve the stresses inside the product and to prevent any further drying of the product.

Providing the drying diagrams are properly applied, it is also possible to improve the color of the pasta in high-temperature drying. On the one hand an enzyme inactivation takes place, and on the other hand the creation of color pigments (Maillard reaction) can be reduced if, with low product moisture, the drying temperature for stabilization is reduced again.

At the end of the stabilization phase, the relative air humidity is increased again to add moisture to the product and to balance the moisture gradient in the product. In the subsequent cooling zone the excess heat is extracted from the product in order to stop desorption. This prevents further drying of the product and reduces the product temperature to the ambient temperature.

For lower capacities, a single-housing drier (see Fig. 4) will suffice, where the entire drying process takes place in the first housing. The main drying zone B1 is then located in the upper segment, and stabilization (C1) is carried out in the bottom section (B2 in Fig. 4).

Figure 4. Bühler C-line short goods line with single housing drier

3.3.5. Intermediate Storage

To allow efficient and economic operation, today's production lines are in service around the clock. They are only stopped for maintenance and cleaning. On the other hand, packaging of the finished products is typically done in one- or two-shift operation. This, of course, requires a possibility of storing the products while the packaging line is shut down. Depending on the specific product shapes and the line capacity, various options are available.

Short Goods Bins. For so-called rolling short good shapes such as bows, rigatoni, penne, etc., storage bins are excellently suited and likely the most economic solution. The products are transferred from the cooler via a bucket elevator and belt conveyors to the storage bins and are retrieved from storage again by belt conveyors, which move them to the packaging lines. Care must be taken to ensure that no bulky products are stored in the bins, because the resulting high weight would cause the products to break under their own load. Moreover, bulky products have

poor flow characteristics, affecting discharge from the storage bins.

Short Goods Belt Stackers. For storage of bulky products such as noodles, belt stackers are used. As a result of the very shallow depth of product on the individual belts of the stacker, the weight of the product is low so that degradation of the products is prevented.

Long Goods Stacker. After discharge from the cooler, the loaded sticks are automatically transferred to the stacker. The product is held in intermediate storage on several tiers, hanging from the sticks. When the packaging line is started, this also automatically activates the stripping and cutting machine at the outlet of the stacker. There, the product is stripped from the sticks, cut to the proper length and transferred to the packaging line via cascades. The trimmed-off bends and ends are conveyed pneumatically to the regrinding system described above. The empty sticks are returned to the spreader by a stick return system, which is installed underneath the drier elements.

Nidi and Twisted Goods Stacker. In the same way as with the short goods stacker, the product here is stored on belts. But as nidi and twisted goods require very gentle treatment, bucket conveyors are used instead of elevators and belt conveyors for feed and discharge.

3.3.6. Thermal and Electrical Infrastructures

The energy consumption of state-of-the-art pasta production lines equals that of traditional production systems. The energy costs (oil, electric power, cooling, steam) account for about 2 % of the total production cost. In view of the high cost of energy, the manufacturers of pasta production equipment are forced to give consideration also to this point. They must therefore manufacture machinery operating with the highest possible economy and minimum energy losses.

Heating. For heating the driers, hot water is used. Depending on the required drying temperature, the water must have an inlet temperature as high as 130°C. In many cases, this will require the use of a pressure system. The most proven design for a heating system is one equipped with a primary and a secondary circuit for each drier. This enables very accurate and fast temperature control.

Steam as a heating medium for driers has proven inadequate, since steam is too sluggish to allow fast temperature changes. If a steam heating system is installed, hot water is generated in heat exchangers.

The size of the heating boiler depends entirely on the line capacity. As an approximate value, a heating capacity of about 24 000 kJ/h can be assumed, based on a pasta output of 100 kg/h.

Electric Power. For the total power supply of all motors of a production line including the extrusion press, about 11–13 kW must be assumed, based on a pasta output of 100 kg/h. Here, too, the actual consumption values are about 20–25 % lower.

Power consumption for the bin storage system and the packaging equipment depends on the design of these installations and must be defined on a case-by-case basis.

Cooling. For the extrusion press barrel and the cooler after the drying line, cold water is used as a cooling medium. Per 100 kg/h line capacity, about 10 500 kJ/h must be assumed.

Steam. Steam is used only for steam injection during the starting and stopping phases. The most suitable type of steam is saturated steam of max. 1 bar pressure.

Compressed Air. To actuate the valves of the bin storage system and the packaging equipment plus those on the production line, a compressed air system is installed.

3.3.7. Pasta Quality

High-quality pasta products are smooth, hard and to a certain extent resilient or elastic. They should be transparent and have a rich yellow color (depending on the raw material used).

Long goods, especially spaghetti, must withstand considerable flexing stresses without breaking. Fracture surfaces must have a neat

and glassy appearance. Of course, the quality of pasta becomes apparent when consumed.

Pasta swells during cooking and absorbs water. Good products absorb up to double their own weight of water or even more. Their volume will increase three- or four-fold.

Good pasta retains its shape and has a certain "bite" (al dente characteristics).

If properly stored, pasta has a shelf life of several years.

4. Modified Flours

4.1. Definition and Possible Applications

Modified flours are thermally or mechanically treated cereal products, which have many different applications in food industries. Therefore, those products have to meet special, adapted, and functional requirements. This asks for the use of an extremely flexible process technology for the production of modified flours. The requirements can be achieved with the help of cooking extrusion technology such as HTST (high temperature, short time) treatment. Table 3 lists different products and the corresponding use of modified flour.

Table 3. Applications of modified flours in food industries

Baking industry	Binder for water, prolongation of freshness
Sauces	binder, thickening agent
Soups	thickening agent
Sausages	binder, binder for water
Meat, fish	filler, adhesive agent for breadcrumbs, breadcrumbs
Tablets	substrate, replaces modified starches
Deserts	binder for water, thickener
Baby food	basis, carrier for calories, thickener

A thermal or mechanical treatment means that flour, together with water, under application of heat and shearing, is kept for a certain time above the gelatinization temperature of starches. During this time, defined physical changes of the functional properties of the product, like viscosity behavior, water absorption index and water solubility index or cold-paste viscosity, occur.

4.2. Production

4.2.1. Process

A simple thermal treatment of cereal flours can be carried out industrially with the help of autoclaves, jet cookers with spray driers or drum driers, flour heat treatment, etc. However, using cooking extrusion, a variable thermal and mechanical treatment can be achieved.

The most important criteria for the desired product properties and qualities are the process and the setting of parameters of temperature and pressure. In cooking extrusion technology, the introduction of energy into the matter can be achieved by feeding steam into the product above or directly into the extruder. This can be done by convection via the barrels or by energy dissipation via shearing. Heating up and preswelling of flours in preconditioners is nowadays widely applied. By varying the ratio between thermal and mechanical energy introduction, a direct influence on structural changes, e.g., the molecular decomposition of starch, can be taken.

Thus, the functional properties of modified flours can be influenced systematically. The direct characteristic correlation of the structure is described in [8].

Furthermore, extrusion is distinguished by its continuous operation at short term and high temperatures and pressures, resulting in lower production costs compared to traditional processes. This is mainly caused by lower investment costs at reduced space and human resource requirements.

In addition, the process is very flexible and easy to adapt to market needs concerning throughput and product quality together with a simple controllability.

4.2.2. Production Plant for Modified Flours

Extrusion plants for the production of modified flours are already proven in industrial application in throughput ranges from 200 kg/h up to 4000 kg/h. The plants include the following process steps: premixing, dosing/feeding, preconditioning, extruding, drying, grinding, and sifting and, if necessary, mixing/blending and packaging.

Figure 5. Flowsheet of a plant for the production of modified flours (Source: Bühler) [9]

The flours can be premixed with other ingredients and are then fed by continuous dosing into the preconditioner, where they are mixed intensively with water and steam to achieve a hydrothermal pretreatment of the blend. Due to the thermal modification quite high degrees of gelatinization of the starch can be achieved already. Thus, if sufficient water is added, the high amount of starch contained, e.g., in wheat flour can be gelatinized to more then 95 % (as determined by differential scanning calorimetry, DSC).

The following extruder mixes, shears, cooks, and plastifies a dough and afterwards presses it through a die. In consequence of the resulting difference in pressure from inside the die to atmospheric conditions, the product expands and partly dries by an abrupt evaporation of the steam. The extrudates are then transported pneumatically into a drier. Depending on the desired water content of the finished product, the extrudates will be dried and subsequently ground. After milling, the material is sifted to classify it into the desired granulation ranges. Figure 5 shows an example of a flowsheet of a plant for the production of modified flours.

4.3. Technological Aspects of Extrusion Cooking

Under the conditions of extrusion cooking, depending on the process variables, the functional properties of the flours are significantly changed. The reactions occurring inside the extruder are multidimensional and depend on a wide range of machine- and raw material-specific process parameters. Due to these multidimensional reactions, a differentiation of the influence of the single parameters on the product properties is hardly possible.

Therefore, an analytic model of the system was developed. It partitions the process in partial stages and differentiates between material properties, variable and fixed process parameters, system parameters, product changes, and product properties.

Figure 6. Overview over the unit operations of the cooking extrusion process (Bühler)

A systematic approach allows to specifically differentiate the influences of the extrusion parameters on the properties of the modified flours and allows further to use the knowledge about these dependencies.

Figure 6 depicts the extrusion process on the basis of an analytic model and gives an overview on the possible unit operations.

To understand this model, it is important to know which processes take place inside the extruder and how they occur.

An exemplary course of temperature and filling degree over the whole length of the extrusion process is shown in Figure 7. From that a specific time-temperature behavior for a certain point of process results.

Inside the preconditioner, flours are intensively mixed with 5–25 % water and up to 7 % steam. Thus, each particle of flour is heated up immediately with the help of condensation heat and on its surface the water is equally distributed to achieve an easy, quick, and complete penetration.

In this way the swelling of the starch granules up to high degrees of pregelatinization is induced. The pregelatinized flour is then directly fed into the extruder. There, it is also possible to feed additional water or direct steam to exactly control the introduction of energy into the matter to reach the desired product properties.

Figure 7. Schematic illustration of profile lines inside the cooking extruder

By possible feed of additional water into the mixing zone the bulk material is transferred into a dough. The matter is then transported into the plastification zone, where it is exposed to shear forces by increasing the filling degree, the pressure and under influence of the speed of the screws. Thus a dissipation of energy is caused which partly is transformed into heat.

This causes a further decomposition of the material up to a complete decomposition and plastification of the starch granules. The causative parameters for this modification are the water content, the temperature, the introduction of mechanical energy and the pressure. Inside the extruder it is possible to consecutively place multiple plastification and tension release zones, which enables to stepwise shearing and releasing the product to specifically set some temperature peaks. Thus, damaging of the material can be controlled exactly.

After the mixing and shearing zone, the material passes the dwelling or reaction zone at increased temperature. In the following zone directly before the die pressure is built up and additional energy is introduced. Filling degree and dissipation of energy are increasing. Thus, the temperature rises again. Before the die, the dough is plastified, whereas the contained water is finely dispersed. As a result of the high pressure of approx. 20–150 bar and temperatures between 120 and 180°C the water is not in the vapor, but still in the liquid state. Forced by the screw conveying action of the extruder the cooked mass is pressed through the die and then immediately cut by a rotating knife. Under the abruptly upcoming atmospheric conditions, the water contained in the dough is promptly evaporized and blows up the elastic dough. Caused by the finely dispersed droplets of water, each droplet results in a bubble and a foamy structure occurs. The expanded vapor exhausts, thus the whole process is named a drying by expansion. Via the aforementioned parameter, the degree of expansion can be controlled.

The evaporation of about 5–10 % of water effects—by removal of the evaporation heat—a quick cooling and hardening. The generated foamy structure will persist.

4.4. Effects of the Process Variables on Parameters and Functional Properties of Modified Flours

As a result of trials performed by the Bühler company and other published analyses [8, 10, 11] the following relations and functional dependencies could be hypothesized.

4.4.1. Effect of Process Variables on Parameters

The cold-paste viscosity can clearly be described in dependence of the water content at given machine and process parameters by the system parameters specific mechanic energy introduction and specific thermal energy introduction. Caused by the available water in the dough, the viscosity of the dough in the extruder and hence the resistance of the screws inside the extruder is influenced by the product, whereby shear stress and dissipation of energy are predetermined. Depending on the water content, at otherwise constant conditions, a wide range of qualities can be produced

- from almost burned product, at highest energy introduction and very high temperatures inside the dough,
- over dextrinized flour, thus highly decomposed products with lowest cold-paste viscosity, and
- maximal gelatinized starch with highest cold-paste viscosity,
- up to partly cooked and uncooked products at very high water contents and very low introduction of energy.

Dependencies of the Process Variables. Screw speed and water content have influence on specific mechanical energy (SME) introduced in the product. A rising screw speed causes increasing of the shear rate. This means higher SME and thus the temperature of the material rises. With low water content, the viscosity of the dough inside the process section of the extruder is much higher and thus the introduction of energy by increased shear stress rises significantly, resulting in a higher end temperature of the product. Along with the introduction of energy, caused by the degradation of ingredients a decrease in viscosity results and thus the pressure before the dies does not rise accordingly.

4.4.2. Effect of Parameters on Functional Properties

The functional properties of the finished products such as indices of water absorption and

water solubility and cold-paste viscosity depend strongly on the conditions prevailing inside the extruder, i.e., on the parameters, specific mechanical energy input, resulting temperature, and retention time.

The water absorption increases enormously with decreasing energy input and decreases slightly with increasing temperature of the material. The water solubility increases with increasing energy input, i.e., with increasing SME or also temperature. The cold-paste viscosity increases strongly with decreasing specific energy input. All three functional properties depend also on the water content.

4.4.3. Effect of Functional Properties on Finished Products

Definitions for the definite impacts of those parameters on the finished products can only be generalized to a very limited extent, because all producers of finished products containing modified flours have their specific recipes, whose specific composition have to fulfill the requirements of the corresponding markets. However, the recipes will not be published by the producers.

An exception are the publications of the German Federal Research Institute for Cereals [12, 13], in which the behavior of viscosity and the impact of extruded wheat flours on the quality properties of pastries and wheat bread are discussed. It was detected that addition of 5–20 % of modified flour to filo dough caused desired changes in the rheology of the dough. The pleasant impression of short chewing and the freshness were improved. An addition of 5 % of modified flour to a wheat bread dough resulted in an increased dough and bread yield at higher water binding capacity. Also here, the freshness was improved.

Physical alterations of flours to reach specific product properties become more and more important. This is caused by increased demands on the produced food as well as by the increasing necessity to declare all additives, as requested by EU directives. Due to the increasing restrictions regarding the authorization of chemical additives for flours, more and more alternative solutions have to be found and used to reach the same effect as with chemical agents. The treatment of flours by HTST extrusion enables production of a wide range of those products, whereas in general no additives have to be used, because modified flours are simply cooked and sheared under pressure with the only addition of water.

5. Breakfast Cereals

5.1. Definition and Historical Background

End of 19th century ready to eat (RTE) breakfast cereals were among the first deliberately conceived "health foods," developed in Battle Creek, Michigan, USA to make more palatable the diets based on whole grains that were advocated then. Some of the processes and products developed in the early days of the cereals industry are still in use.

Early products included flakes made from corn grits and wheat berries, shredded wheat biscuits, and nuggets of barley and other ingredients baked in loaves and then milled and dried. Today, RTE cereals are profitable and diverse segments of major food companies. A big player in the market collectively is the category of private-label cereals made by several small- to medium-sized firms.

The private-label products are usually imitations of the branded products, but sell for less because they have lower marketing costs, the companies do not invest as much in research, and sometimes use less expensive processes.

5.2. Processes

The major cereal processes are: cooking, flaking, gun puffing, shredding, and extrusion.

5.2.1. Batch Cooking

As described in [14] the early cereal production included separate mixing, cooking, forming, drying and coating steps. Typically, many of these process steps were, and often still are, batch operations. For example, whole wheat berries or corn grits are cooked in pressure vessels with added malt, salt, and other ingredients

using direct steam injection. The objective is to gelatinize the starch and temper the grains with enough moisture to make them plastic without turning them to soft mush.

After cooking, the grains are cooled and slightly dried before forming by passing between polished steel rolls to form flakes. Whole grain rice is also cooked and then lightly "bumped" between rolls before forming by toasting in an oven.

In the traditional flake process, flakes from the rolls are dried and toasted in conveyor ovens. Some modern ovens use high velocity jets to fluidize the bed of flakes and shorten the drying time.

If flakes have to be coated with sugar or flavors, they pass through a coating drum or belt and then are dried again. Coated or uncoated flakes often have a vitamin emulsion sprayed on them as a final step, followed by another drying step and then packaging. The vitamins and minerals, if used, are added last because they would not survive the high temperature treatments or earlier process steps.

Breakfast cereals are seen as desirable vehicles for delivery of added nutrients because they can represent a significant portion of a daily diet, are usually eaten with milk, and have wide appeal. Often, nutrient fortification is an important part of a given brand's image and marketing message.

5.2.2. Gun Puffing

Gun puffing starts with cereal flour or whole grains, depending on the products. Some producer make puffed whole wheat and rice, while others use oat flour and other ingredients to make some expanded products. Flour-based products are formed using low-pressure extruders, similar to those used for pasta. The pellets are dried and then heated in a closed pressure vessel. The pellets are released from the elevated pressure either by quickly opening a closure or by transfer through a special valve. The sudden pressure change in the softened pellet causes expansion of water vapor and quick cooling, so that the pellet expands and then hardens. The porous shape retains a crunchy texture even in milk.

Puffed pieces are dried further, coated and enriched as mentioned earlier, and packaged.

5.2.3. Shredding

Shredding involves cooking whole grains to a precise moisture content and then passing them through batteries of special rolls in which one roll is grooved and presses against a smooth roll. High pressures are developed as the grain is forced into the grooves, so the rolls tend to be short to control deflection. In a commercial line, there are many banks of rolls. The threads of wheat are laid over one another in mats and cut into biscuits. A variation is to have cross grooves so that threads are attached to one another.

In some processes, cooked grains may be stored in a relatively moist state before forming. It may be that this step contributes to final flavor by permitting chemical and biochemical reactions to occur. In general, it is observed that the traditional, batch, relatively slow processes seem to produce the more complex flavored products, though there are constant efforts to increase speed and efficiency.

5.2.4. Cooking Extrusion

One of the great improvements in cereal processing was the application of cooking extrusion. An extruder can combine in one machine the operations of mixing, cooking, forming, and expansion. At the time when cooking extrusion began, no extruders existed that were intended for foods, thus cereal producers used equipment from the plastics industry. Today, food extruders are produced by many manufacturers. For a more detailed description of the technological aspects of extrusion cooking, see Section 4.3.

Because flours rather than intact berries or grits are generally used for production of extruded cereal products, and because HTST processes are employed, it is a great challenge to match with extrusion technology the flavor and texture of more traditionally made products. The goal of the branded cereal makers is to deliver good taste in combination with healthy nutrition. Lately, this has meant a focus on products from whole grains with high bran or fiber content. Fibers are essentially inert and interfere with expansion. Some products can be made by alternative processes, such as gun puffing or extrusion.

Flakes can be made by extruding pellets and then flaking those pellets. This permits use of flour and incorporation of other ingredients in comparison with using whole berries or grains.

5.2.5. Coating and Inclusions

Sugar coating is a complex topic in its own way. Coatings may be transparent or opaque and may include artificial sweeteners such as aspartame and noncariogenic materials such as sugar alcohols. High-solids coating solutions must be kept hot and are subject to discoloration. Application can be challenging because the solutions can crystallize and harden quickly.

Fruits, such as raisins, have been added to cereals for many years, but in the search for new products, other inclusions, such as nuts, freeze-dried fruit, yogurt and granola (a cereal mix itself) have been added. These create processing challenges in feeding at correct rates, prevention of segregation, matching moisture activity, and preventing creation of fines.

The water activities of raisins and cereal flakes are quite different, for instance, so that when enclosed in a sealed package, the flakes can become soggy and the raisins dried out. Early packaging used waxed paper in cardboard boxes, which actually permitted some moisture to escape. When cereal packaging was changed to polymer liners, which are better moisture barriers, the equilibration issue became more noticeable. One solution has been to add solids to the raisins, such as sugar or cereal fines coatings, to reduce water activity.

Fines are an almost inevitable byproduct of cereal manufacture and have become a useful ingredient in other products, such as breadings and coatings.

Ready to eat cereals are an interesting food category not only for the variety and challenges of the many processes, but also for the several ways in which they can be analyzed. There are cereals for adults and for children; sweetened and unsweetened; short-lived novelties and 100-year-old standards; originals and copies; whole grain and flour-based; branded and private label. For manufacturers, RTE cereal has been profitable, challenging, and a sources of technical accomplishment. For consumers, it continues to be nutritious, enjoyable, and generally a good value.

5.2.6. Production Plant for Breakfast Cereals

Extrusion plants for the production of breakfast cereals are for a long time proven in industrial applications in throughput ranges from 200 kg/h up to 2500 kg/h. Figure 8 gives an example of a production plant.

Breakfast cereal plants can include the following production steps: premixing, feeding, preconditioning, extruding, predrying, flaking, toasting / cooling, coating and final drying.

The premixed raw materials are fed to the preconditioner, where they are mixed intensively with water and steam to achieve a hydrothermal pretreatment. A high degree of pregelatinization can be achieved already. Inside the extruder the material is further mixed, sheared, cooked and plastified. The dough is then pressed through the extruder die.

In case of the production of *direct expanded cereals*, the temperature at the die has to be higher then 100°C and the pressure must be higher than product elasticity and atmospheric pressure. In consequence of the hence resulting difference in pressure and temperature from inside the die to atmospheric conditions, the product will expand and partly dry by an abrupt evaporation of the steam. The moisture content of direct expanded products after being cut at the die is about 8–12 %. The extruded products is then transported to the drier and afterwards eventually to a coating drum to apply, e.g., a sugar coating and then to the final drier. The finished product will have a moisture content of below 3–4 %.

In case of *indirect expanded products*, e.g., corn flakes, the expansion at the die should be prevented. Therefore, the temperature of the material before the die has to be lower than 100°C and the pressure should not exceed the sum of product elasticity and ambient pressure. To achieve this, at the end of the process section of the extruder degassing for the evaporation of steam and cooling has to take place.

The extruded pellets have a moisture content of about 20–22 % and are pneumatically transported to an intermediate drier. Here, mainly the

Figure 8. Example of a production plant for breakfast cereals based on extrusion (source: Bühler)

surface is dried to prevent the pellets sticking together and an equalization of moisture distribution inside the pellet takes place. After the intermediate drying step, the pellets are flaked with about 16–18 % water. The expansion of the corn flakes and thus the development of the bubbly crunchy texture of corn flakes take place in the toaster. Temperatures of above 250°C lead to an immediate evaporation of part of the moisture content inside the flakes and thus to an expansion. The finished corn flakes can then optionally be sugar-coated and dried.

Corn flakes also have a moisture content of below 3–4 %.

6. Reconstituted and Fortified Cereal Grains, e.g., Rice Kernels

One of the most fundamental decisions underlying food fortification schemes is selecting appropriate foods to be fortified with the essential micronutrients lacking in a population's diet. Criteria to identify potential food fortification vehicles generally include selecting a food that is commonly eaten by the target groups, is affordable and available all year long, and is processed in such a manner that fortification is technically feasible and can be done economically. Staple foods such as wheat flour and sugar have been popular foods to fortify in order to address micronutrient deficiencies in several developing countries.

6.1. Importance of Rice as a Food

It has been estimated by Juliano [15] that half the world's population subsists wholly or partially on rice. Globally, rice accounts for 22 % of total energy intake [16]. Ninety percent of the world crop is grown and consumed in Asia. American consumption, although increasing, is still only about 11 kg per person annually, as compared with 90–181 kg per person in parts of Asia [1]. Rice is the only major cereal crop that is primarily consumed by humans directly as harvested, and only wheat and corn are produced in comparable quantity.

The trends in rice consumption are closely linked to rice production in a number of rice-producing countries as illustrated in Figure 9.

Low energy and protein intakes are common nutritional problems for people in rice consuming countries. The FAO estimates that about half the population of South Asia do not have adequate energy intakes. Nutrition indicators compiled for 34 rice-consuming countries indicate that the incidence of low birth weight, infant mortality, mortality of children fewer than five years of age, and prevalence of underweight children are considerably higher in these countries than in other countries [17].

Figure 9. Percent calories contributed by stable foods to diets–all developing countries (Source: FAO/ESS (averages 1992-1994))

6.2. Rice Milling and Nutrient Losses

Milling of rice is different from that of other cereals, because the objective is to produce a maximum yield of unbroken milled grains rather than a flour or meal as in the case of most other cereal grains. Processing the unhulled rice grain (also called paddy or rough rice) involves cleaning, milling to remove the hull, germ, and bran layers, and sizing to produce white uncoated rice. A coating of talc and glucose may be added to improve appearance; however, this is not permitted in some countries. Milled or white rice represents 40–76 % extraction of rough rice. The B vitamins and iron are found primarily in the germ and bran layers, and are therefore removed in the milling process. It has been estimated that in the course of milling brown rice to white rice approximately 80 % of the thiamine is removed [18]. Other nutrients contained in the bran layer are also lost, including niacin, iron, and riboflavin.

Nutrients can be preserved in the rice grain by parboiling (see → Cereals, Chap. 7.6). Parboiling transfers the nutrients contained in the bran layer to the inner endosperm layer prior to milling and removal of the bran. The parboiling process involves soaking of rough rice and applying heat and then drying and milling. Parboiled rice is produced in India, Bangladesh, Burma, Thailand, Sri Lanka, and other Asian countries by both traditional and modern parboiling processes [19]. Parboiling may require expensive equipment and can result in golden color rice that is often not acceptable to consumers. Converted rice was developed with a similar process but uses pressure to transfer nutrients to the inner endosperm layer. Enrichment methods have been developed to add synthetic vitamins and minerals to rice to replace those lost in milling. Primarily iron, thiamine, niacin, and riboflavin are added, although other nutrients, including pantothenic acid, vitamin B6, calcium, and folate have also been included in some enrichment premixes. In addition, rice has been used as a vehicle for vitamin A fortification in various pilot programs.

6.3. Extrusion Process for the Production of Tailor-Made Rice Products

Using cooking extruders it is possible to produce granules, which are similar to rice kernels, out of broken rice or rice flour. By setting the optimal process parameter and recipes, those extruded rice granules can feature a wide range of formats and properties. The main features of the rice granules such as color, shape, size, and texture, ingredient composition, cooking behavior and optionally also the digestion properties can be determined and tailor-made for each application due to process and recipe settings.

Figure 10 illustrates the main process steps in the production of extruded rice granules. Figure 11 shows a possible implementation into a machinery flowsheet.

Figure 10. Main steps in the production of reconstituted rice

Figure 11. Flowsheet of a production line for reconstituted rice (Source:Bühler)

Due to their adaptable properties, the extruded rice granules can be used for different applications. Depending on the process parameters, the granules can be used as instant rice granules, as quick cooking rice granules with a coking time of 2–7 min or as an additive to mix into natural rice.

6.3.1. Quick-Cooking Rice

Two quick-cooking rice products exist: quick-cooking rice granules and quick-cooking rice kernels produced from natural rice kernels. *Quick-cooking rice kernels* can be produced with the help of diverse thermal processes out of dehulled, whole rice kernels. They have cooking times between 8 and 14 min. Such quick-cooking rice is only hardly to differentiate from, e.g., parboiled rice.

Quick-cooking rice granules, produced with the help of a cooking extrusion process, are used for similar applications as traditionally manufactured quick-cooking rice, i.e., often packed in transparent packing. Therefore, their appearance is highly important. A reconstituted rice granule should optically not differ from traditionally manufactured quick cooking rice. But also the texture should not be different because quick cooking rice is mostly used as a stand-alone product, e.g., as a side dish with meat. A rice product which differs too much from natural rice would not generate satisfied customers.

6.3.2. Instant Rice

Before the introduction of rehydration, all instant rice products available on the market differed substantially from the appearance of natural rice. Instant rice is produced by intensive cooking or steaming with a following drying process. During these process steps, the original shape of the rice kernels is more or less lost. Due to the rehydration with hot or even boiling water, the optical and sensory differences to natural rice will largely disappear.

Instant rice, manufactured with extruders show the same properties. The kernels show a certain expansion and a porous surface, which enables a quick absorption of the water during rehydration. The optical similarity to natural rice is in this application not very important because those kernels are mostly already mixed with other ingredients together in a menu, which has only to be doused by hot water. Thus the single kernels are not eyed as such. Here, after rehydration, “only” the texture has to be correct.

6.3.3. Additive Product

To be accepted by customers, rice granules which are added to natural rice to increase the yield, have to have a similar appearance as the other kernels. Also the texture is very important and, the larger the percentage of reconstituted rice, the more important becomes the similarity.

The specialty within this application is the cooking time. Rice granules which are produces with extruders have per se a short cooking time. When they are mixed with natural rice, their texture has still to be pleasing at the time the natural rice is cooked. This is rather significant because the ratio of reconstituted rice granules can be up to 10–20 % (refers to the fraction of broken rice during milling).

A variation of the cooking stability and thus of the texture of the rehydrated rice can be done by setting of different parameter. Grinding of rice and thereby the choice of the right granulation can influence the texture, whereas fine flours lead to a more soft and sticky texture than finer or coarser semolina. Raw materials coarser then 1000 µm can influence the optical quality because a less smooth surface of the kernel can

be generated. Besides this, the cooking stability can be influenced by additives mixed to the raw material. Substances which supply cross-linkers, such as sulfur or phosphates, can create a networking of the flour ingredients which leads to a strengthening of the matrix. Some dietary fibers or hydrocolloids can also be utilized to influence the stability of the matrix, so that during the much longer cooking time of natural kernels the reconstituted rice granules as much as possible keep their form, texture and appearance.

6.3.4. Fortification of Reconstituted Rice

A further option is the possibility to add functional ingredients during the extrusion process. Hereby, the fortification, respectively the addition of several substances to the extruded rice granules is possible. For such a fortification several conditions have to be fulfilled. The additives must be stable to temperature (short term up to 120°C) and shear, so that the desired content can be reached under economically maintainable conditions. Furthermore, the influence of the additives on the production process has to be taken into consideration. An unsuitable riboflavin formulation, e.g., can lead to a yellow colored "curry rice". In case of addition of an unsuitable iron formulation, oxidation can create a brownish product.

Basically all substances known as functional ingredients are suitable as additives. The main groups are vitamins (especially of groups A and B), minerals, and trace elements (e.g., Ca, Fe, Mg, Se,. . .), proteins or several essential amino acids, fatty acids, antioxidants as well as the so-called pro- and prebiotic ingredients, such as oligosaccharides and dietary fibers. Finally all substances can be added which are accepted by customers and whose benefit can be communicated. Thus very special products can be tailor-made for diverse markets and applications. For those regions of the world, where nutritional deficiencies caused by the nearly exclusive consumption of rice occur, fortified rice kernels can be produced which can improve the deficiencies of vitamin A and other vitamins and minerals.

An interesting form to supply a huge percentage of population with essential nutrients is the possibility to produce rice granules with a high concentration of additives, so that the recommended amount of the added vitamins and minerals can be provided by addition of those kernels to normal white rice in the ratio 1:100 or even 1:200. The production of the highly fortified kernels can be organized centrally, whereas the addition to white rice can take place in each small rice mill all over the country.

By the addition of the corresponding vitamins or minerals, products can be specified for the particular deficiencies of different population groups, e.g., for older people or children by feeding in school.

The potential to use ionic liquids as novel solvents or fluids for a diverse range of applications has become increasingly apparent. The intrinsic nonvolatile nature of ILs provides an opportunity to reduce, or even completely eliminate, hazardous and toxic emissions to the atmosphere, thus providing the promise for significant environmental benefits. In synthesis and catalysis, ILs have been used as solvents (or solvents and catalysts), with the greatest current effort on using the ILs as alternatives to volatile organic compounds (VOCs). Electrochemical studies have utilized the fact that ILs are liquids rather than solids to provide liquid

10.1002/14356007.l14_l01

electrolytes without needing to add an additional solvent. Ionic liquids are also used in separations, replacing volatile solvents. The number of applications on pilot-plant and commercial scale is still limited, but growing.Although ionic liquids are also known as "green solvents", this is not always true. They can be corrosive, flammable, or toxic. Due to their nonvolatile nature, ionic liquids are generally considered as having a low impact on the environment and human health, and thus recognized as solvents for green chemistry. However, the impact of ionic liquids on aquatic ecosystems is important given their mild to high solubility in water. Before ionic liquids will be widely used in industry, the effects of ILs on the aquatic environment must be known.

Nomenclature of ionic liquids

Cations:
[Rmim] 1-R-3-methylimidazolium
[Rbupy] 4-R-*N*-butylpyridinium
[mRpyrr] *N*-methyl-*N*-R-pyrrolidinium
[N4111] butyl-trimethyl ammonium
[P4111] butyl-trimethyl phosphonium
[S4111] butyl-trimethyl sulfonium
R: H hydrogen
m methyl
e ethyl
p propyl
b butyl
h(e) hexyl
o(c) octyl
Anions
[Tf_2N] bis(trifluoromethylsulfonyl)imide $[(CF_3SO_2)_2N]^-$
[triflate] trifluoromethanesulfonate $[CF_3SO_3]^-$
[tosylate] toluene sulfonate $[CH_3C_6H_4SO_3]^-$
[trifluoroacetate] $[CF_3CO_2]^-$

1. Introduction [1 – 9]

The common definition of ionic liquids (ILs), or room temperature ionic liquids (RTILs), is that they are liquids that are composed entirely of ions and are fluid below 100 °C. Heating normal salts, such as sodium chloride (NaCl, *mp* 801 °C), to high temperature produces also a liquid, that consists entirely of ions, but this is a molten salt and not defined as an ionic liquid. Ionic liquids are organic salts that are liquid at low temperatures (< 100 °C) and consist of large bulky and asymmetric organic cations based on methylimidazolium [Rmim], *N*-butylpyridinium [R−N−bupy], *N*-methyl−*N*-alkylpyrrolidinium, quaternary ammonium, quaternary phosphonium ions (Fig. 1.), and many others; and anions such as hexafluorophosphate $[PF_6]^-$, tetrafluoroborate $[BF_4]^-$, alkylsulfates $[RSO_4]^-$, alkylsulfonates $[RSO_3]^-$, halides as chloride $[Cl]^-$, bromide $[Br]^-$ or iodide $[I]^-$, nitrate $[NO_3]^-$, sulfate $[SO_4]^-$, aluminum chloride $[AlCl_4]^-$, triflate $[CF_3SO_3]^-$, bis(trifluoromethylsulfonyl)imide $[(CF_3SO_2)_2N = Tf_2N]^-$, etc. [10 – 19].

Figure 1. Structure of 1-R-3-methylimidazolium, 4-R-*N*-butylpyridinium, *N*-methyl-*N*-R-pyrrolidinium, quaternary ammonium and quaternary phosphonium cations

The R group of the cation is variable, typical are alkyl chains such as methyl, ethyl, butyl, etc., but can also be any of a variety of other functional groups (e.g., fluoroalkyl, alkenyl, methoxy). The variability of the anion and R groups in the imidazolium, pyridinium, pyrrolidinium, ammonium or phosphonium cations may be used to adjust the properties of the ionic liquids. Therefore, the possibility arises to optimize the ionic liquid for a specific application by stepwise tuning the relevant solvent properties. For this reason ionic liquids have been referred to as "designer solvents" in several publications [13]. Presently, there are more than 1000 different ionic liquids available, but it has been demonstrated [20] that there will be at least 10^6 simple ionic liquids, that can be easily prepared in the laboratory. There will be 10^{12} binary combinations of these and 10^{18} ternary systems possible. It is entirely plausible that to generate the required combination of reactivity, solubility and viscosity, industrial applications will need to work with ternary systems [21].

Ionic liquids have a wide liquidus range, ranging from 75 °C to 300 °C, which allows a

better kinetic control on reactions. The liquidus region is defined as the range of temperatures between the normal freezing point and boiling point. Thus, water has a 100 °C liquidus range. The narrow liquidus range of common solvents means that they are all relatively volatile at process conditions.

Due to the fact that an ionic liquid is a salt, it has a negligible vapor pressure. Therefore, ionic liquids are not volatile at process conditions. Furthermore, they are nonflammable, have a high thermal stability and a high ionic conductivity. These properties permit their use in many fields. They are used as reaction media to substitute VOCs, as homogeneous catalysts, and as extractive media in liquid – liquid extraction processes [1 – 19]. However, the use of ionic liquids also has some disadvantages: the physical properties are not always known, their viscosity is usually higher than that of common solvents and their toxicity is unknown. For a successful application of ionic liquids in industrial processes, these aspects must be taken into consideration.

2. Physical and Chemical Properties

2.1. Introduction

The notable characteristics of ionic liquids are their nonmeasurable vapor pressure (however, several authors have actually shown in a recent paper that there is a small but non negligible vapor pressure [22]), nonflammability (decomposition products of ILs can, however, be flammable [23]), thermal stability, wide liquid range, and solvating properties for diverse kinds of materials. Another important feature of ionic liquids is their designability: miscibility with water or organic solvents can be tuned through side chain lengths on the cation and choice of anion. Furthermore, they can be functionalized to act as acids, bases, or ligands.

The change of anion dramatically affects the chemical behavior and stability of the ionic liquid, and the change of cation has a profound effect on the physical properties, such as melting point, viscosity, and density [24 – 28]. Cations are typically big, bulky and asymmetric, accounting for the low melting points. Increasing the length of an alkyl chain tends to decrease water solubility by increasing the hydrophobicity of the cation. In addition, chemical and physical properties can be changed dramatically by the choice of anion. For example, imidazolium salts with halide, acetate, nitrate and trifluoroacetate anions are totally miscible with water, while $[PF_6]^-$ and $[(CF_3SO_2)_2N]^-$ imidazolium salts are immiscible, and $[BF_4]^-$ and $[CF_3SO_3]^-$ imidazolium salts can be totally miscible or immiscible depending on the substituents on the cation [26]. The anions are chosen to control the chemistry [29] and the cations are chosen to determine the physical properties [27]. In this way, a vast range of ionic liquids can be created. The number of possible anions [30 – 33] and cations [34 – 36] is rapidly increasing.

Ionic liquids possess the following desirable properties [37]:

- Liquidus range of 300 °C (−96 – +200 °C)
- Excellent solvents for organic, inorganic, and polymeric materials
- Acidic compositions are superacids ($pK_a \approx -20$)
- Some are water-sensitive; others are hydrophobic and air-stable
- Thermally stable under conditions up to 500 °C
- Easy to buy and simple to prepare
- No measurable vapor pressure
- Nonflammable
- Exhibit Brønsted, Lewis, Franklin, and 'super' acidity
- Highly solvating — therefore low volumes used, implying process intensification
- Catalysts as well as solvents
- Highly selective reactions

2.2. Melting Points [9]

Ionic liquids have been defined to have melting points below 100 °C and most of them are liquid at room temperature. Both cations and anions contribute to the low meting points of ionic liquids. The increase in anion size leads to a decrease in melting point [16]. For example, the melting points of 1-ethyl-3-methylimidazolium type ionic liquids with different anions, such as $[BF_4]^-$, $[Tf_2N]^-$ and $[C_2H_5SO_4]^-$ are 15 °C [38], −3 °C [32] and −20 °C, respectively (see Table 1). Size and symmetry of the cations make an important impact on the melting points

of ionic liquids and melting point generally increases with increasing substituents chain length. Large cations and increased asymmetric substitution results in a melting point reduction [39]. This can be readily seen by examining the phase diagrams for the hexafluorophosphate salts [24, 25], where the melting point shows a pronounced dependence on the chain length.

2.3. Density [9]

Ionic liquids in general are denser than water with values ranging from 1 to 1.6 g/cm^3 and their densities decrease with increase in the length of the alkyl chain in the cation [41], as is seen in Table 1, where densities of some ionic liquids and common solvents are shown. The order of increasing density for ionic liquids composed of a single cation is: $[CH_3SO_3]^- \approx [BF_4]^- < [CF_3CO_2]^- < [CF_3SO_3]^- < [C_3F_7CO_2]^- < [(CF_3SO_2)_2N]^-$ [51]. The densities of ionic liquids decrease almost linearly with increasing temperatures [46].

The densities of ionic liquids are also affected by the identity of anions. For example, the densities of 1-butyl-3-methylimidazolium type ionic liquids with different anions, such as $[BF_4]^-$, $[PF_6]^-$, and $[Tf_2N]^-$ are 1.2 g/cm^3, 1.37 g/cm^3 and 1.43 g/cm^3, respectively (Table 1).

2.4. Viscosity [9]

Generally, ionic liquids are more viscous than common molecular solvents and their viscosities are ranging from 10 mPa · s to about 500 mPa · s at room temperature. The viscosities of some popular air- and water-stable ionic liquids and common solvents at room temperature are summarized in Table 1. The viscosity of ionic liquids is determined by van der Waals forces and hydrogen bonding. Alkyl chain lengthening in the cation leads to an increase in viscosity [32], due to stronger van der Waals forces between cations leading to increase in the energy required for molecular motion. Also, the ability of anions to form hydrogen bonding has a pronounced effect on viscosity. The fluorinated anions such as $[BF_4]^-$ and $[PF_6]^-$ form viscous ionic liquids due to the formation of complexes with hydrogen bonding donors [40]. Electrostatic forces may also play an important role. In general, all ionic liquids show a significant decrease in viscosity as the temperature increases [26, 27, 46, 47, 52]. Ionic liquids should be free of impurities or moisture, because contamination of the ILs with chloride led to an increase of the viscosity [26, 27], see for instance the viscosities of several ILs in Table 1, measured by different authors.

2.5. Thermal stability

Ionic liquids can be thermally stable up to 500 °C. The thermal stability of ionic liquids is limited by the strength of their heteroatom – carbon and their heteroatom – hydrogen bonds, respectively [16]. The ionic liquids 1-ethyl-3-methylimidazolium tetrafluoroborate, 1-butyl-3-methylimdazolium tetrafluoroborate and 1,2-dimethyl-3-propylimidazolium bis(trifluorosulfonyl)imide are stable up to temperatures of 445, 423 and 457 °C, respectively [53]. However, the long-term thermal stability of ionic liquids containing dicyanamide or tricyanomethide anions is significantly lower than might be expected from temperature-ramped thermogravimetric analysis (TGA) studies, and these anions, combined with N-based cations, yield polymeric products during thermal decomposition [54].

2.6. Electrochemical Window [9]

The electrochemical window is an important property and plays a key role in using ionic liquids in electrodeposition of metals and semiconductors. By definition, the electrochemical window is the electrochemical potential range over which the electrolyte is neither reduced nor oxidized at an electrode. This value determines the electrochemical stability of solvents. As known, the electrodeposition of elements and compounds in water is limited by its low electrochemical window of only about 1.2 V. On the contrary, ionic liquids have significantly larger electrochemical windows, e.g., 4.15 V for [bmim][PF_6] at a platinum electrode [55], 4.10 V for [bmim][BF_4] [55] and 5.5 V for [bmpyrr][Tf_2N] at a glassy carbon electrode [56]. In general, the wide electrochemical windows of ionic liquids have opened the door

Table 1. Melting points, densities and viscosities of selected liquids at 20 °C

Liquid	*mp*, °C	Density, g/mL	Viscosity, mPa · s
Ethanol	−117.3	0.7893	1.200

to electrodeposit metals and semiconductors at room temperature which were formerly obtained only from high temperature molten salts. For example, Al, Mg, Si, Ge, and rare earth elements can be won from room temperature ionic liquids. The thermal stability of ionic liquids allows to electrodeposit Ta, Nb, V, Se, and presumably many other elements at elevated temperature.

3. Synthesis/Production [14, 16, 57]

The first ionic liquid, ethylammonium nitrate, was produced in 1914 [58]. This compound was formed by the addition of concentrated nitric acid to ethylamine, after which water was removed by distillation to give the pure salt, which was liquid at room temperature (*mp* 12 °C). The protonation of suitable starting materials, such as amines and phosphines, still represents the simplest method for the formation of ionic liquids, but, unfortunately, it can only be applied for a few useful salts. Most ILs are formed from cations that do not contain acidic protons.

The synthesis of ILs can generally be split into two parts: formation of the desired cation, and anion exchange to form the desired product (see Fig. 2.) [16]. Quaternization of an amine or phosphine, for example, is the initial step in the synthesis of the cation of an ionic liquid [59 – 61]. If it is not possible to form the desired anion directly by the quaternization reaction, a further step is required (synthesis steps IIa or IIb in Fig. 2.).

Figure 2. Typical synthesis path for the formation of ionic liquids [0]

The anion exchange of ionic liquids can be divided into three distinct paths: direct treatment of halide salts, such as an ammonium halide $[R'R_3N]^+X^-$, with Lewis acids, MX_y, most notably $AlCl_3$ (synthesis step IIa, Fig. 2.) [59, 62 – 74], the formation of ionic liquids by metathesis (synthesis step IIb, Fig. 2.), and acid – base neutralization reactions.

3.1. Lewis Acid-Based ILs

In the first case (step IIa), several anion species are often present in equilibrium, which depends on the ratio of the two components $[R'R_3N]^+X^-$ and MX_y (Eq. **??**).

The direct treatment of 1-ethyl-3-methylimidazolium chloride ([emim][Cl]) with different ratios of Lewis acids, mostly $AlCl_3$, can form the following ionic liquids: [emim][$AlCl_4$], [emim][Al_2Cl_7] or [emim][Al_3Cl_{10}]. Other Lewis acids include $AlEtCl_2$ [65, 66], BCl_3 [67] CuCl [68] and $SnCl_2$ [69]. These kind of ionic liquids form the first generation ionic liquids. A major disadvantage of these ILs is that they are water-sensitive and can decompose in the presence of water, forming HCl.

3.2. Anion Metathesis

The second route, metathesis, can be carried out by the addition of a metal salt $M^+[A]^-$, for instance a Group 1 metal, silver, or ammonium salt (with precipitation of M^+X^-), over an ion exchanger [70] or by displacement of the halide ion by a strong acid $H^+[A]^-$ (with the release of H^+X^-) (synthesis step IIb, Fig. 2.). Many alkylammonium halides are commercially available or they can be prepared simply by the reaction of the appropriate halogenoalkane and amine. Preparation of the pyridinium and imidazolium halides can be achieved similarly [75, 76]. The synthesis of [emim][Cl] was reported in1982 [59] and the synthesis of [bmim][Cl] in 1997 [77].

In 1992, the first of the new ionic liquids, [emim][BF_4], was prepared via metathesis of [emim][I] with $AgBF_4$ in methanol [48]. This salt has a melting point of 12 °C and may be prepared more cheaply using [NH_4][BF_4] in acetone [38]. This ease of preparation, together with its relative moisture stability and its immiscibility with a number of organic solvents is leading to its increasing use in biphasic catalysis. The preparation of [emim][PF_6] was accomplished by reaction of [emim][Cl] with HPF_6 [78, 79]. This salt has a melting point of 60 °C, which makes it slightly less attractive than the $[BF_4]^-$ salt. Examples of ILs prepared by anion metathesis are ILs with $[PF_6]^-$ [12, 24, 78, 79]; $[BF_4]^-$ [24, 48, 78 – 80]; $[CF_3SO_2)_2N]^-$ [32, 79]; $[CF_3SO_3]^-$ [32, 81]; $[CH_3CO_2]^-$ [48], $[CF_3CO_2]^-$ [48]; $[CF_3(CF_2)_3CO_2]^-$ [32]; $[NO_3]^-$ [26, 32, 79]; $[CB_{11}H_{12}]^-$ [82]; $[N(CN)_2]^-$ [83] and $[AuCl_4]^-$ [84].

Low-melting salts have been prepared by anion-exchange reactions for many years. The preparation of tetrahexylammonium benzoate, a liquid at 25 °C, was already reported in 1967 [85]. Ionic liquids based on cations such as tetrabutylphosphonium [86] and trimethylsulfonium [87] also have been prepared by similar synthetic methods.

The ILs [Rmim][PF_6] are by far the most popular ionic liquids used, because they are cheap, easy to prepare and to purify, are excellent archetypes for structural studies and are effectively free of IPR (Intellectual Property Rights) issues, but they are water-sensitive and will form HF at higher temperatures [88]. For this reason, these ILs will never be used in industry. The reaction of the $[PF_6]^-$ anion proceeds as follows:

ILs with thiocyanate, nonafluorobutanesulfonate, bis((trifluoromethyl)sulfonyl)imide, tris((trifluoromethyl)sulfonyl)methide, trifluoroacetate, and heptafluorobutanoate salts have all been prepared by metathesis reactions [32, 89, 90]. The metathesis reaction can leave the ionic liquids contaminated with a small amount of halide ions that may react with solute materials [91].

Tetraalkylammonium tetraalkylborides are usually prepared by the metathesis reaction of tetraalkylammonium bromide and lithium tetraalkylboride [92, 93]. Since both the ammonium cation and the boride anion are asymmetrically substituted, the starting materials are usually made rather than purchased. Reaction of a trialkylborane with the appropriate alkyllithium reagent in dry hexane yields the required lithium tetraalkylboride [94].

Other ionic liquids are made by the quarternization of the appropriate amine. This has been used to prepare a number of 1-Alkyl-3-ethylimidazolium trifluoromethanesulfonate salts [32]. Methyl triflate is reacted with a stoichiometric amount of the 1-alkylimidazole in 1,1,1-trichloromethane. Since the methyl triflate is sensitive to moisture, the reaction must be carried out under anhydrous conditions.

Monoalkylammonium nitrate salts are best prepared by the neutralization of aqueous solutions of the amine with nitric acid [90]. The ionic liquids are isolated by removing excess water in vacuum. In a similar reaction, tetraalkylammonium sulfonates have been prepared by mixing equimolar amounts of the sulfonic acid and the tetraalkylammonium hydroxide [95]. Excess water was also here removed in vacuum. To ensure the purity of the ionic liquids, they were dissolved in either acetonitrile or tetrahydrofuran and treated with activated charcoal for at least 24 h, and finally the organic solvent was removed in vacuum. The metathesis reaction can also be carried out entirely in organic solvents, such as CH_2Cl_2 [79] or acetone [81].

The final method for the synthesis of ionic liquids is direct combination of a halide salt with a metal halide. This is how the halogenoaluminate(III) and the chlorocuprate(I) ionic liquids are prepared [92, 96]. The chlorocuprate(I) ionic liquids are particularly sensitive to oxygen and have not found widespread use in synthesis [97].

3.2.1. Synthesis of Chloride-Free ILs

New low-cost ionic liquids containing methyl and ethyl sulfate anions can be easily and efficiently prepared under ambient conditions by the reaction of 1-alkylimidazoles with dimethyl sulfate and diethyl sulfate. The preparation and characterization of a series of 1,3-dialkylimidazolium alkyl sulfate and 1,2,3-trialkylimidazolium alkyl sulfate salts are reported in [98]. 1,3-Dialkylimidazolium salts containing at least one nonmethyl *N*-alkyl substituent are liquids at, or below, room temperature. The salts are stable, water-soluble, inherently 'chloride-free', display an electrochemical window of greater than 4 V, and can be used as alternatives to the corresponding halide salts in metathesis reactions to prepare other ionic liquids including 1-butyl-3-methylimidazolium hexafluorophosphate.

Not all ionic liquids are based around aromatic nitrogen-containing cations, there are also those with tetraalkylphosphonium cations [69, 99 – 109] and tetraalkylammonium cations [21, 110].

3.2.2. Preparation with Microwaves

ILs exhibit excellent heat-transfer properties and efficient absorption/transfer of microwaves and these properties have led to expeditions into "solvent-free" microwave-assisted synthesis routes of ILs. Moreover, the use of microwave synthesis has considerably speeded up ionic liquid synthesis, as well as making their synthesis a model of green chemistry, being stoichiometric, requiring no or low molar excess, and quantitative [111 – 116].

3.3. Producers

Since large-scale applications of ILs are essentially nonexisting, most ILs are prepared on a small scale for laboratory use only. Therefore, it is not surprising that currently most of the IL manufacturers are known as suppliers of laboratory chemicals. Producers of ILs on a ton scale are BASF, Degussa, and Solvent Innovation.

Present major producers/suppliers of ionic liquids are: Acros Organics, Belgium; BASF (imidazolium-based ILs), Germany [117]; Covalent Associates, USA [118]; C-Tri, South Korea; Cytec (phosphonium-based ILs), Canada/USA [105 – 107, 119]; Degussa, Germany; IoLiTec, Germany; Merck (EMD in the USA), Germany [120 – 122]; Ozark, USA, Sachem (ammonium based ILs), USA [123, 124]; Scionix (choline-based ILs), United Kingdom [125]; Sigma-Aldrich/Fluka; Solvent Innovation, Germany [126 – 128]; Strem Chemicals (phosphonium ILs), USA; TCI, Japan.

4. Applications

Until 1998, the number of entries with the terms "ionic liquid" or "ionic liquids" in the Chemical Abstracts was below or around twenty per year,

but this number is increasing from 45 per year in 1999 to 1255 per year in 2005 and 1717 in 2006. The total number of entries is now over 5300. Since the interest in ionic liquids has only increased after 1999, the development of ionic liquids is still mostly in the research phase. Therefore, there are only a few industrial applications known. However, there is a large field of potentially interesting applications. This section is divided in two parts: one dealing with applications still in the research phase and one with applications in the pilot-plant and industrial phase.

4.1. Potential applications

Most of the potential applications of ionic liquids are as solvents or catalysts in many kinds of chemical reactions such as Diels–Alder and Friedel–Crafts reactions, and also as very suitable solvents for biocatalysis. Applications in other fields, such as in separations, are lower in numbers.

4.1.1. Solvents for Synthesis and Catalysis [1 – 6, 14 – 17, 129 – 141]

Room-temperature ionic liquids have the potential to provide environmentally friendly solvents for the chemical and pharmaceutical industries because of their nonvolatile nature. Many reactions have been demonstrated in IL solvents, although in some cases without any obvious benefits over other solvents. The nature of the IL components can significantly influence reaction outcomes, either as catalysts, or modifying the reactivity of components. The activity of nucleophiles in ILs can be moderated by the anion of the IL [134, 135]. This 'buffering' action is effectively utilized [29], demonstrating how different reaction outcomes are obtained from IL+HNO_3 systems depending on the different anions present in the IL solvent.

4.1.1.1. Applications in Reactions and Catalysis [37]:

- Friedel–Crafts Alkylation [142 – 152]
- Heck and Suzuki coupling[153 – 156]
- Oxidation (with air and/or pure oxygen) [157]
- Cracking [158]
- Reduction
- Hydrogenation [159 – 161]
- Chiral hydrogenation
- Oligomerization
- Polymerization [162 – 165]
- Sulfonation
- Nitration
- Halogenation [166]
- Diazotization
- Diels–Alder reactions [167]

4.1.1.2. Solvents for Catalysis [181]

Molten tetraalkylphosphonium and ammonium salts were investigated as reaction solvents/catalysts for industrial hydroformylation and hydrogenation reactions [69, 99 – 101]. Since ILs are stable, nonvolatile solvents and since the product may be separated by decantation or simple distillation [69], these properties are now considered fundamental to the application of ILs as solvents for clean syntheses. Many homogeneous catalysis reactions have subsequently been demonstrated [3, 4, 14 – 17, 133 – 140]. In cases where reactions proceed through ionic transition states, ILs can be used to tailor the transition metal complexes central to the catalyst systems, offer novel routes to new compounds, and opportunities for reaction control and separation of the homogeneous catalysts from the reactants, products and the substrate [182 – 184].

Palladium-catalyzed Heck couplings have been extensively investigated [153 – 156] and ILs are presumably the best solvents for these reactions [186]. Acid-catalyzed reactions [187] including Friedel – Crafts alkylations [142 – 152] and olefin alkylation, oligomerization, and polymerization have been studied [188]. Synthetic polyalphaolefins base oils and lubricants [189] can be prepared efficiently utilizing the ability to control acidity of the IL catalyst and the relative solubility of feedstocks and products. The Institut Français du Petrole (IFP) has developed an IL-liquid biphasic analogue of their existing mersol X process [190] for propene and butene

dimerization. The IL system uses an IL as solvent for the Ni(II) catalyst [191] with a large decrease in catalyst consumption, increased selectivity to octene, and a significant reduction in the need for downstream neutralization of entrained catalyst in the product stream.

4.1.1.3. Polymer Synthesis

The use of ILs in polymer synthesis is a recent development and it is still limited [162 – 165]. In the last few years, however, it has been shown that ionic liquids can be advantageously used also for polymer synthesis. In radical polymerization, an increase of k_p/k_t ratio for polymerizations conducted in ionic liquids has been observed. Application of ionic liquids as solvents for atom transfer radical polymerization facilitates separation of the polymer from residual catalyst and reduces the extent of side reactions. Significant increases in the rate of polymer propagation to termination steps in radical polymerization have been shown and potential applications in the preparation of specialist polymers are suggested, especially controlling formation of block copolymers, and IL-polymer gel electrolytes.

4.1.1.4. Biocatalysis

Attention has recently been focused on the use of enzymes in ionic liquids [136, 168 – 178]. It was already noted that enzymes can be relatively stable in a mixture of ILs and water. The enzyme displayed excellent stability when suspended in the ionic liquid and the activity was equal to that observed in ethyl acetate – water.

Several groups have reported on lipase-catalyzed enantioselective transesterification of chiral alcohols in ionic liquids [178 – 180]. The kinetic resolution of 1-phenylethanol with nine different lipases in ten different ionic liquids was investigated [178]. Good activities and, in many cases, improved enantioselectivities were observed compared with the same reaction in methyl *tert*-butyl ether (MTBE). Based on these initial studies the use of enzymes in ionic liquids would appear to open up a new field of nonaqueous enzymology. Ionic liquids could have added benefits for performing biotransformations with highly polar substrates, e.g., carbohydrates and amino acids, which are sparingly soluble in common organic solvents.

4.1.2. Electrochemical Applications [181]

ILs can be designed with wide electrochemical windows and high electrically conductivity [192]. When combined with wide liquid ranges and thermal stability, ILs can be used in place of traditional solvent-based electrolytes for a wide range of metal-purification, plating, and refining processes, increasing the scope of electrochemical reactions. Many IL-based electrochemical devices have been developed, including batteries [38, 59, 193 – 196], capacitors [197 – 199], and solar cells [33, 200, 201]. IL electrolytic systems are also useful for electrosynthesis [202] and electrodeposition of metals [203 – 206].

4.1.3. Analytical Applications

ILs are increasingly used in analytical chemistry, such as in chromatography, MS, spectroscopy, and electrochemistry [90, 207 – 213]. They are, for instance, employed as stationary phases in gas – liquid chromatography, because of their high viscosity, high thermal stability, low vapor pressure and wetting ability toward common supports such as fused-silica capillary tubing.

4.1.4. Separations

4.1.4.1. Liquid Separations

The use of ionic liquids in separations is presently mostly in the extraction of metal ions with [bmim][PF_6], [hmim][PF_6] and other $[PF_6]^-$ based ILs and with $[Tf_2N]^-$ based ILs [214 – 218]; of alcohols using [Rmim][PF_6] (R = butyl, pentyl, heptyl, or octyl) and [emim][Tf_2N] [219 – 221]; separation of alcohols and alkanes or alkenes with [omim][Cl], [hmim][BF_4] or [hmim][PF_6] [222, 223]; desulfurization of oils with [emim][$AlCl_4$], [bmim][$AlCl_4$], [bmim][BF_4], [bmim][PF_6], trimethylamine hydrochloride/$AlCl_3$, [emim][ethyl sulfate] and [bmim][octyl sulfate] [224 – 227]; and separation of ethers from ethanol with [omim][Cl]

and [bmim] [trifluoromethanesulfonate] [228, 229]. It is also possible to separate compounds from each other by selective transport by using supported liquid membranes based on ionic liquids, such as [bmim][PF_6] [230 – 233]. Environmental pollutants, such as aromatic and polycyclic aromatic hydrocarbons, can be extracted from aqueous solutions with ionic liquids [bmim][PF_6] and [omim][PF_6] [233]. There are only a few publications concerning extraction of aromatic hydrocarbons from mixtures of aromatic and aliphatic hydrocarbons, notably with [emim][I_3], [bmim][I_3], [emim][$(CF_3SO_2)_2N$], [omim][Cl] and trimethylamine chloride/$AlCl_3$, [hmim][BF_4] and [hmim][PF_6] [234 – 238].

High toluene/heptane selectivities were obtained with ionic liquids [mebupy][BF_4], [mebupy][CH_3SO_4], [bmim][BF_4] at 40 °C and 75 °C and with [emim][tosylate] at 75 °C. With [mebupy][BF_4], also extraction experiments with other aromatic/aliphatic combinations were carried out and high aromatic/aliphatic selectivities were obtained [239 – 244].

Using salts to break azeotropes by interacting preferentially with one component is a well established industrial procedure. The ability of ILs to break azeotropes has been described for ethanol – water, acetone – methanol, THF – water and acetic acid – water mixtures [235, 238].

It is remarkable that most of the ionic liquids used for extraction of the compounds mentioned are PF_6^--containing imidazolium-based ionic liquids. The reason is that these ionic liquids are very versatile and easy to prepare, although HF formation is likely [88].

4.1.4.2. Gas Separations

Ionic liquids can also be used for gas separations, mainly the removal of CO_2 from several gases [245 – 253], but also for ethylene – ethane or propene – propane separations [246, 254 – 259]. The CO_2 solubility is larger in ILs with anions such as $[Tf_2N]^-$, and $[methide]^-$, which contain fluoroalkyl groups, regardless whether the cation is imidazolium, pyrrolidinium, or tetraalkylammonium. These results suggest that the nature of the anion has the most significant influence on the gas solubilities [245, 246]. An increase in the alkyl chain length on the cation increases the CO_2 solubility marginally. Oxygen is hardly soluble in several ionic liquids and the solubility of CO is below the detection limit [246]. For the separation of hydrocarbon gases it was found that the solubility increased as the number of carbons increased, and also when the number of carbon double bonds increased [254 – 256].

4.1.5. Fluid Applications: Thermal Fluids and Lubricants [181]

The possible use of ILs as *thermal heat-transfer fluids* has been investigated at a research level [53, 260]; heat capacity, thermal stability and liquidus range are potentially competitive with commercial diphenyl ether and polysiloxane heat-transfer fluids.

The similarity in appearance of most ILs to oils makes their possible use as *lubricants* an obvious area of interest. Initial studies show significant promise as lubricants for a range of metal and ceramic interfaces [261 – 264]. Researchers from Alcoa [265] have also recently reported an assessment of two ILs as base oils for rolling aluminum sheet. The ILs performed comparably to current blended polyalphaolefins although problems with the poor solubility of traditional lubricant additives were anticipated. In each case here, the range of available ILs with differing physical characteristics means that appropriate IL for the specific application can be selected.

4.2. Applications in Pilot Plants and Industry

An overview of applications of ionic liquids on pilot plant and industrial scale is given in Table 2.

4.2.1. Reactions

4.2.1.1. Acid Scavenging

Since 2002, BASF is operating the first commercial multi-ton process employing ionic liquids [266 – 272], called the BASIL (Biphasic Acid Scavenging utilizing Ionic Liquids) process. The BASIL process is a general solution for all kinds of acid scavenging problems [268, 273].

Table 2. Overview of pilot plant and industrial applications of ionic liquids

Company	Process	IL is acting as . . .	Scale
BASF	acid scavenging	auxiliary	commercial
Eastman Chemical	production of 2,5-dihydrofuran	catalyst	commercial until 2004
BASF	chlorination	solvent	commercial
Eli Lilly	cleavage of ethers	catalyst/reagent	pilot
Degussa	hydrosilylation	solvent	pilot
Arkema	fluorination	solvent	pilot
IFP	olefin dimerization	solvent	pilot
Chevron Phillips	olefin oligomerization	catalyst	pilot
BASF	extractive distillation	extractant	pilot
University of Twente	extraction	extractant	pilot
Scionix	electroplating (Cr)	electrolyte	pilot
Degussa	compatibilizer	performance additive	commercial
Iolitec/Wandres	cleaning fluid	performance additive	commercial
Air Products	storage of gases	liquid support	pilot
Linde	gas compression	liquid piston	pilot

The BASIL process is utilized in a plant producing diethoxyphenylphosphine, a photoinitiator intermediate prepared by the reaction of dichlorophenylphosphene with ethanol. The reaction generates HCl as a byproduct, which must be removed to avoid an unwanted side reaction (see Fig. 3.).

Figure 3. Synthesis of diethoxyphenylphosphine

The acid is normally removed by adding a tertiary amine, but this generates an ammonium salt slurry that is difficult to filter from the reaction mixture. BASF adds now 1-methylimidazole, which forms 1-methyimidazolium chloride (*mp* 75 °C) (Fig. 4.).

Figure 4. Synthesis of diethoxyphenylphosphine with 1-methylimidazole

After the reaction, two phases are formed, which can easily be separated: an upper phase of pure product and a lower phase of pure IL. The IL formed is deprotonated, regenerating the 1-methyimidazole for reuse. The space – time yield for the formation of an alkoxyphenylphosphine was thus increased from 8 kg $\cdot$ m^{-3} $\cdot$ h^{-1} to 690 000 kg $\cdot$ m^{-3} $\cdot$ h^{-1}, a factor of 80 000 increased productivity. The new, very small jet reactor is shown in Figure 5. BASF has successfully started a dedicated plant using this jet stream reactor technology end of 2004.

Figure 5. BASIL process in a little jet reactor (courtesy of BASF AG)

4.2.1.2. Production of 2,5-Dihydrofuran

In 1996, Eastman Chemical launched a cocatalyst ionic liquid system for the synthesis of 2,5-dihydrofuran. This compound is an intermediate in the production of many commodity, specialty, and fine chemicals. The continuous liquid-phase process uses a trialkyltin iodide Lewis acid and a tetraalkylphosphonium iodide ionic liquid to catalyze the rearrangement of 3,4-epoxy-1-butene to 2,5-dihydrofuran.

The continuous rearrangement process requires that the catalysts are essentially nonvolatile so that they do not codistill with the product. The cocatalyst system gives a high selectivity for 2,5-dihydrofuran and provides an efficient means for catalyst recovery [274 – 277].

The process was operated by Texas Eastman Division in a plant with a capacity of 1 400 t/a at Longview. Although the process was a technical success, the plant was shut down in December 2004 for business reasons, when Eastman exited from production of fine chemicals.

4.2.1.3. Chlorination of Alcohols/Cleavage of Ethers

In principle, exchange of the OH groups of alcohols by chlorine can be effected by reaction with HCl gas. Unfortunately, in the case of diols usually less than 100 % conversion is achieved and the reaction stops after formation of cyclic or open-chain ethers. Surprisingly, the reactivity profile completely changes when the reaction is performed in an ionic liquid. Obviously, either the nucleophilicity of HCl or the nucleofugicity of the leaving group (water) is drastically increased. Apparently, the ether side products are cleaved, allowing for a further reaction to the desired bischlorinated product. Figure 6. shows how selectivities improve when the chlorination of butanediol is performed in an ionic liquid rather than in an organic solvent [278]. Butanediol is completely soluble in the ionic liquid. When the reaction proceeds, a second, organic phase is formed, which consists of the reaction product 1,4-dichlorobutane. After complete conversion, the organic phase is just separated off. Water which is formed during the reaction is distilled off from the remaining ionic liquid which can be used for the next run without any further work-up.

Figure 6. Higher selectivities for 1,4-dichlorobutane (DCB) are achieved if the chlorination of butanediol with HCl gas is performed in an ionic liquid rather than in the pure alcohol. Side products usually are ethers (tetrahydrofuran, THF, dichlorobutyl ether, DCBE) or the monochlorinated product 1-chlorobutane-4-ol (CBO).

In a process by Eli Lilly aromatic methoxy ethers are cleaved in a pyridinium hydrochloride melt [279]. Usually, the cleavage of aromatic methoxy ethers requires very harsh conditions and inconvenient reagents such as BBr_3 [280] or HBr in boiling acetic acid [281, 282]. 4-Hydroxyphenylbutyric acid has been produced by Eli Lilly on a 190 L pilot scale with yields of > 94 % by reacting 4-methoxyphenylbutyric acid for 2 h at 210 °C in pyridinium hydrochloride ([py][HCl]).

4.2.1.4. Hydrosilylation

Hydrosilylation is a widely used method for the synthesis of organo-modified silanes and siloxanes. The addition of Si-H to C-C double bonds is usually catalyzed by homogenous or colloidal Pt catalysts. The major drawback of this reaction is that the catalyst cannot easily be removed from the product after completion of the reaction. Degussa uses a biphasic approach to perform the hydrosilylation reaction [283, 284], where the catalyst is dispersed in the ionic liquid phase, from which the pure product separates as a new liquid phase that can be easily decanted after the reaction. The ionic liquid catalyst phase is still active and can be reused. It is important that standard hydrosilylation catalysts can be used

without further modifications. Degussa has been running this process on a pilot scale achieving conversions of > 99 %.

4.2.1.5. Fluorination

Hydrofluorocarbons (HFC) can be manufactured from chlorinated hydrocarbons by reacting them with HF to substitute fluorine for chlorine. State-of-the-art catalyst for this reaction is $SbCl_5$. However, this catalyst suffers from a reductive deactivation by formation of Sb(III) species. To overcome the loss of catalyst, chlorine is co-fed for a reoxidation of Sb(III) to Sb(V). This is technically feasible, but consumes chlorine as raw material and leads to back-chlorination of the fluorinated products and hence to significantly lower yields. Arkema has demonstrated on a pilot stage that imidazolium-based ionic liquids with an "SbF_6" anion can eliminate the deactivation problem [285]. The pilot reaction has been running for more than 1000 h exceeding selectivities of 99.5 % and without any noticeable deactivation.

4.2.1.6. Dimerization and Oligomerization of Olefins

IFP has developed an ionic liquid-based process, the biphasic Difasol technology, for the dimerization of butenes on a pilot scale [190, 191, 286 – 288]. Because of the solubility of the catalyst, based on a Ni(II) salt, in the ionic liquid phase, $[bmim]Cl/AlCl_3/C_2H_5AlCl_2$ (1:1.22:0.06 molar ratio), and the poor miscibility of the products, the production unit is essentially reduced to a continuously stirred tank reactor followed by a phase separator. With this process, a more efficient overall catalyst utilization and a significant increase in the yield of octenes is achieved. A dimer selectivity in the range of 90 to 92 % with butene conversion in the range of 80 to 85 % can be obtained with a C_4 feed containing 60 % butenes.

Chevron Phillips has found that it is possible to readily make polyalphaolefins with very high viscosity using an ionic liquid catalyst. The oligomerization reaction can thus be carried out in the absence of organic solvents which have hitherto been used as diluents for the feed [289]. The first component of the oligomerization catalyst is an aluminum halide or an alkyl aluminum halide, such as, for example, aluminum trichloride. The second component is a quaternary ammonium, quaternary phosphonium, or tertiary sulfonium ion. The process produces a synthetic lubricant base oil which is used in a variety of lubricants, including gear oils, greases, and automotive engine lubricants. The pilot process produced commercial quantities of more than 450 t of polyalphaolefins in 2004.

4.2.2. Separations

4.2.2.1. Extractive Distillation

Ionic liquids are suitable as entrainers for a whole range of azeotropic systems [238, 290, 291]. Especially if water is part of the azeotropic mixture, very high separation factors can be achieved, because ionic liquids usually are hygroscopic materials with a strong affinity to water. Figure 7. displays the classic vapor – liquid diagram for THF – water. The dots indicate the change after the addition of ionic liquid. To afford a sufficient separation, the amount of ionic liquid added has to be in the range of 30 to 50 wt %.

Figure 7. Equilibrium phase diagram for the system THF – water. The solid line shows the classic azeotropic mixture. The dots indicate how the azeotrope has been broken after addition of the ionic liquid. The amount of THF in the vapor phase is always larger than in the liquid phase.

As the ionic liquid has no vapor pressure, the entrainer itself need not be distilled, hence a sec-

ond separation column is not required and energy can be saved. A benchmark calculation has revealed that a saving potential of about 37 % for energy cost and 22 % for the investment can be achieved. BASF has run an extractive distillation process in a pilot plant continuously for three months. Although the ionic liquid faced a severe thermal treatment of about 250 °C in the recycling step, it fully kept its performance without a purge.

4.2.2.2. Extraction of Aromatic Hydrocarbons

Extraction of toluene from a mixture of toluene and heptane with the ionic liquid [mebupy][BF_4] was carried out in a pilot plant at the University of Twente [292 – 294]. The pilot extraction unit was a Rotating Disc Column with an inside diameter of 60 mm, 40 stirred compartments and a total active length of 1800 mm (Fig. 8.). The performances of sulfolane and [mebupy][BF_4] as

Figure 8. Pilot Rotating Disc Column for extraction of toluene, inside diameter 60 mm, 40 stirred compartments and a total active length of 1800 mm

the solvent were compared for the extractive removal of 10 wt % toluene from a *n*-heptane feed. When dispersed, the ionic liquid [mebupy][BF_4] appeared to be a better solvent for the toluene – heptane separation than sulfolane. Due to the higher toluene distribution coefficient (0.44 vs. 0.3 for sulfolane), lower solvent-to-feed ratios are required with the IL to extract the same amount of toluene, while compared to sulfolane a 10 % higher flux (volumetric throughput) and similar mass transfer efficiency was obtained. The best performance (highest toluene extraction efficiency) was obtained at the highest rotation speed used (643 rpm) during the extraction experiments. At a flux of 10 $m^3\ m^{-2}\ h^{-1}$ excellent hydrodynamic behavior was observed and three to four equilibrium stages were contained in the 1.80 m high active section of the column.

4.2.3. Electroplating/Polishing

The major disadvantage of the current process of chrome plating is that it requires the use of chromic acid-based electrolytes comprising hexavalent chromium, which is toxic and carcinogenic. Scionix, a joint venture company between the University of Leicester and Whyte Chemicals Ltd, has developed an ionic liquid containing Cr(III) salts [295], which is significantly less toxic than the carcinogenic Cr(VI) species. The process operates with > 90 % current efficiency, resulting in significantly reduced power consumption and making the ionic liquid technology a more environmentally-benign form of plating [296]. Moreover, because there are no aqueous solutions present, hydrogen evolution is negligible, hence essentially crack-free, highly corrosion-resistant deposits are possible. The process has been operated on a 50-L pilot scale and is currently being developed by a number of industrial partners.

Electropolishing of stainless steel is an effective way of increasing corrosion resistance, and decreasing wear in addition to the obvious aesthetic benefits. Scionix had developed a concept to form eutectic-based ionic liquids, from a variety of quaternary ammonium salts, such as choline chloride, and carboxylic acids. The mixture is stable because the chloride ion is complexed by the associated acid rather than mixing quaternary ammonium salts with metal halides [297, 298]. The ionic liquids allow electropolishing with high current efficiency (> 80 %), improved surface finish and improved corrosion resistance [299]. When the metal, and it is usually iron, is electrochemically oxidized, it complexes with the hydrogen-bond donor and the insoluble complex precipitates to the base of the cell. The cell liquid can be filtered periodically and the metal complex is collected. This allows for a suitable recycling of both the ionic liquid and the metal, preventing environmental emissions. The process is currently running in a 1200-L demonstrator module in Birmingham, UK.

Scionix is currently developing a commercially viable medium-to-large-scale electropolishing plant using these novel electrolytes in collaboration with UK based Anopol Ltd.

4.2.4. ILs as Performance Chemicals

4.2.4.1. Compatibilizers for Pigment Pastes

Up to now only very little attention has been paid to ionic liquids as performance chemicals. Degussa has managed to develop an application of ionic liquids as so-called compatibilizers for pigment pastes [300, 301].

Paints and coatings can be tinted by adding a small amount of a color concentrate — the pigment paste — to a white base paint. For environmental reasons, it is preferable to use water-based pigment pastes. However, the water-based systems cannot universally be used for both water- and solvent-based paints. This problem has been solved by addition of ionic liquids to the pigment paste.

4.2.4.2. Antistatic Additives for Cleaning Fluids

Wandres Micro-Cleaning GmbH has developed a cleaning system for high-value surfaces that uses moistened instead of dry filaments [302].

The liquid film (water) is brought onto the filament with the help of very small, micrometer sized water droplets, which are generated in a Venturi nozzle. To avoid electrostatic charging of the surface, a supporting salt is usually added that facilitates electrical conductivity. If sodium chloride is used as a supporting salt, a solid is

precipitated in the nozzle leading to encrustation and plugging of the system. Ionic liquids can offer a unique solution to this problem, since as liquid salts they can provide electrical conductivity without precipitation of a solid, hence without formation of deposits. The ionic liquid solution to this problem was developed and established by Iolitec in cooperation with Wandres Micro-Cleaning GmbH.

4.2.5. ILs in Gas Processing

4.2.5.1. Storage of Gases

The semiconductor manufacturing industry uses a number of hazardous specialty gases such as phosphine (PH_3), arsine (AsH_3) and boron trifluoride (BF_3) for doping, etching, and thin-film deposition. These gases are highly toxic and pyrophoric. Therefore, storage and handling is challenging and requires enormous safety efforts. For example, storage of toxic gases under high pressure in metal cylinders is often unacceptable due to the possibility of leakage or rupture of the cylinder. To overcome the risk of high-pressure storage, these gases are often stored under low pressure by adsorption to solid supports like zeolites [303]. Disadvantages of this technology are low capacities, delivery limitations and low thermal conductivity. Air Products & Chemicals have developed subatmospheric systems based on ionic liquids for storing phosphine (PH_3) and boron trifluoride (BF_3) [304, 305]. Ionic liquids have ideal properties for reversibly storing gases through chemical complexation. Due to the superior heat transfer capability of ionic liquids, gases are easier to load and to deliver, compared to solid adsorption-based systems.

To increase the affinity of the gas to the ionic liquid, a Lewis acid/Lewis base interaction is utilized. This allows for high gas storage capacities without the need for pressure. Phosphine for example is a Lewis base. Accordingly, for the absorption a Lewis acidic ionic liquid such as [bmim][Cu_2Cl_3] is used. Boron trifluoride in turn is a Lewis acid. In this case a Lewis basic ionic liquid like [bmim][BF_4] is used as liquid support (Fig. 9.).

Figure 9. Adsorption/desorption of PH_3 or BF_3 with ionic liquids

Air Products has developed full scale gas packages (2.2-L cylinders), that exhibit excellent gas evolution rates, evolved gas purity, and long-term gas/liquid stability. Commercial PH_3 and BF_3 packages for manufacturing semiconductor devices have been fully qualified at several production facilities.

4.2.5.2. Ionic Compressor

Ionic liquids as so-called engineering fluids or new materials can be a functional part of devices, equipment, and machinery, that will be used in a variety of industries such as automotive, air- and spacecraft, textile, electronics, machinery, or energy. The most remarkable application in this context has been reported by Linde [306]. The so-called "ionic compressor" uses ionic liquids as "liquid piston" allowing for an almost isothermal high pressure compression of gases. Major advantages of this new technology are about ten times higher service times (i.e., operation time without maintenance) and 20 % less energy demand. Moreover, the apparatus is less complex, because it contains only eight rather than some 500 moving parts.

5. Analysis

The purity of an ionic liquid is frequently determined by NMR and other analytical techniques: ^{1}H NMR, ^{13}C NMR spectroscopy [307], mass spectroscopy, and elemental analysis are used to characterize ionic liquids. The crystal structures of IL compounds can be determined by X-ray single crystal diffraction. The powder diffraction method can be used to compare the structural similarities between the single crystal and

the microcrystalline bulk composition. Thermal properties of ionic liquids were studied using thermogravimetry/differential thermal analysis (TG/DTA) and differential thermal calorimetry (DSC) methods [308].

Solvatochromic and fluorescent probe compounds have been utilized to determine the polarity of solvents, including ionic liquids. The application of solvatochromic methods to the characterization of solvent properties of room temperature ionic liquids is discussed in [28]. Gas chromatography is a widely used method for determining thermodynamic properties of pure substances or solvent properties of binary mixtures in which one component, the sample, is generally present at infinite dilution and the other, the stationary phase, is most commonly a nonvolatile liquid. Properties of room-temperature ionic liquids and their solvation properties can thus be derived from measurements by gas chromatography [209].

The structure of ionic liquids can be determined by X-ray absorption fine structure (XAFS) [309], X-ray photoelectron spectroscopy (XPS) or low energy ion scattering (LEIS) [310].

6. Toxicology and Occupational Health

6.1. (Eco)toxicology

Although ionic liquids are also known as "green solvents", they are not always green. They can be corrosive, flammable, or toxic. Due to their nonvolatile nature, ionic liquids are generally considered as having a low impact on the environment and human health, and thus recognized as solvents for green chemistry. However, the impact of ionic liquids on aquatic ecosystems is important given their mild to high solubility in water. Before ionic liquids will be widely used in industry, the effects of ILs on the aquatic environment must be known.

Research into IL aquatic toxicity has shown them to be as toxic as or more so than many current solvents already in use [311]. Ecotoxicological tests, using the OECD standard methods on some ionic liquids, have revealed that several have a very high toxicity towards freshwater algae and the freshwater invertebrate *Daphnia magna*, about 10^4 to 10^6 times more ecotoxic than methanol for the worst cases [312]. Toxicity was greatest for ILs with eight-carbon alkyl chains attached to both imidazolium and pyridinium rings and declined with shorter alkyl chains, indicating a positive relationship between alkyl chain length and toxicity [313, 314]. ILs containing 10, 11, 12 and 14 carbon atoms in an alkoxy group show very high antimicrobial activity [315, 316]. Toxicity appeared to be related to the imidazolium cation and not to the various anions (e.g., Cl^-, Br^-, PF_6^-, and BF_4^-) [317]. Most of the commercially available anions showed no or only marginal cytotoxic effects [318]. However, for certain anions, e.g., $[(C_2F_5)_3PF_3]^-$, $[SbF_6]^-$, $[N(CF_3)_2]^-$, [bis-[1,2-benzenediolato (2-)]borate]$^-$, a significant influence on the ionic liquid cytotoxicity was demonstrated.

Besides the well-established link between toxicity and alkyl chain length on imidazolium, pyridinium, and quaternary ammonium-based ionic liquids, models predict that toxicity increases slightly with the number of nitrogen atoms in an aromatic cation ring. All other things being equal, toxicity is expected to show the trend with cation type of ammonium $<$ pyridinium $<$ imidazolium $<$ triazolium $<$ tetrazolium. In addition, toxicity is expected to decrease with ring methylation as well as with an increase in the number of negatively charged atoms on the cation. The anion plays a secondary role in toxicity for the compounds studied here, although the presence of positively charged atoms on the anion are predicted to slightly increase toxicity [319].

More data is becoming available, such as on cytotoxicity [320], toxicity to *Caenorhabditis elegans* [321], *Oocystis submarina*, and *Cyclotella meneghiniana* [322], resistance to biodegradation [323 – 325] and effects on the growth of lactic acid-producing bacteria [326, 327] and on zebra fish (*Danio rerio*) [311]. Imidazolium and pyridinium ILs inhibit the enzyme acetylcholinesterase, but bulky phosphonium ILs were less inhibitory [328].

A strategy using the structural formula of ionic liquids to generate qualitative and semi-quantitative information in regard to structure – activity relationships (SAR) is presented in [329], accompanied by (eco)toxicological rapid

screening tests [330]. Furthermore, a systematic algorithm was presented to analyze the structure of ionic liquids with respect to the molecular interaction potential within different biotic and abiotic systems [331].

6.2. Mutagenicity

Several ionic liquids were assessed for mutagenicity using the Ames test [332]. The ionic liquids tested were imidazolium based ILs ([bmim][Br], [hmim][Br] and [omim][Br]), pyridinium based ILs ([mebupy][Br], [mehepy][Br] and [meocpy][Br]), and quaternary ammonium based ILs ([4m-amm][Br], [4e-amm][Br], [4b-amm][Br] and [4h-amm][Br]). The Ames test for mutagenicity indicated that none of the ILs tested caused frameshift or missense mutations. Only some ILs, [bmim][Br] and [omim][Br], indicated trends toward potential mutagenicity at high doses, but did not meet the USEPA criteria for classification as a mutagen.

6.3. Safety and Corrosion

The nonflammability of ionic liquids is often highlighted as a safety advantage of ILs over volatile organic compounds (VOCs), but the fact that many ILs are not flammable themselves does not mean that they are safe to use near fire and/or heat sources. A large group of ILs (including commercially available ILs) are combustible due to the nature of their positive heats of formation, oxygen content, and decomposition products (see Fig. 10.) [23].

Figure 10. Ignition test of 1 g of protonated [1-bu-3-H-im][NO_3]

The corrosivity for a given metal is determined by the chemical structure of the IL cation and the nature of the anion. Negative effects were observed with tosylate and dimethylphosphate anions. Dilution with water could lead to hydrolysis of many anions used in ILs which then produce acids (e.g. HF, HCl, sulfuric or phosphoric acid) and, hence, cause acid corrosion. The best performance in all seven IL media tested was observed with stainless steel 304 [333]. Also several other ionic liquids, such as [emim]I_3 and [bmim]$_3$, are very corrosive [239], probably caused by the anion. The corrosion behavior of several metals and metal alloys (copper, nickel, AISI 1018 steel, brass, Inconel 600) exposed to a typical ionic liquid, the 1-butyl-3-methyl-imidazolium bis(trifluoromethanesulfonyl) imide, ([bmim][Tf_2N]), has been investigated by electrochemical and weight-loss methods [334]. At room temperature, there is hardly any corrosion, but at temperatures > 70 °C, the corrosion current for copper dramatically increases showing a strongly dependence on temperature.

The ILs [Rmim][PF_6] are by far the most popular ionic liquids used, because they are cheap, easy to prepare and to purify, are excellent archetypes for structural studies and are effectively free of IPR issues, but they are water sensitive and will form HF at higher temperatures [88].

Nuclear magnetic resonance imaging plays an increasingly important role in the investigation of processes and reactions. It introduces a wide range of contrast parameters that make it suitable for combining the well-established spectroscopic performance of NMR spectroscopy with schemes for obtaining spatially resolved data. Clinical magnetic resonance imaging (MRI) is already a standard diagnostic tool with ever-increasing capabilities, more flexible detection schemes, and fast acquisition being developed. Nonclinical MRI can benefit from this development, but it is required to solve quite different problems with the same basic methodology: noninvasive process control, reaction monitoring, materials studies, transport phenomena, and quality control are some of the topics encountered in industrial chemistry. This article summarizes the necessary background of NMR imaging and the parameters that usually enter into the image information or can be extracted from it at the control of the experimenter. In particular, the use and effect of pulsed field gradients for encoding position and motion is discussed. A number of fast imaging methods are presented which are employed for routine use, and focus is put on the monitoring of transport processes, which are of particular interest to the field. Finally, some essential guidelines regarding the use of particular hardware are given, and the strategies for imaging liquid, solid, and gaseous substances are described.

1. Introduction

Nuclear magnetic resonance imaging and industrial chemistry — an unusual combination? It is true that NMR imaging has not entered the factory environment on a routine basis yet. What most nonspecialists know about NMR can be summarized by two different applications that have the physical principle in common, but rely on different and highly specialized commercial hardware. The first is NMR spectroscopy, which indeed is used routinely not only in academia and research centers, but also in a wide range of companies, with the goal of following synthesis processes or to perform quality control on chemical substances in off-line or on-line mode. Secondly, imaging techniques [commonly known

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.l17_l01

as magnetic resonance imaging (MRI) or MR tomography] have found their most potent commercial application in medical scanners that are available in most major hospitals nowadays, and have been employed for an ever-increasing number of specific applications developing out of traditional brain and spine monitoring towards routine investigations of joints, soft tissue, and lungs.

Because clinical MRI is optimized for the particular problem of imaging large objects (i.e., humans) with medium spatial resolution (1–3 mm)within an acceptable timescale (typically $<$ 30 min), it is of limited usefulness for other applications; besides, the high degree of specialization has led to rather cost-intensive hardware solutions. However, the same physical principles that govern the imaging of tissue can be used for objects of arbitrary shape and size between micrometers and meters. The development of hardware that allows one to perform imaging protocols with superconducting magnets and spectrometers very similar to those used for spectroscopy have widened the field during the last decade to include materials studies and transport phenomena. This laboratory-based technology, often called NMR microscopy (indeed, it provides submillimeter resolution but is normally not on a par with the performance of optical microscopy), has been used to investigate complex structures by means of detecting the NMR signal of solid, liquid, or gas phases, and to monitor transport and reaction within these systems. They are suitable for fundamental studies on real-scale or purpose-built devices. More recent approaches attempt to provide in situ capabilities, e.g., quality control or process control at the production site itself. Because of the need for portability and flexibility, they often rely on lightweight and, consequently, low magnetic field equipment which is subject to loss of sensitivity and imaging capabilities. However, a number of promising attempts have been made to exploit the principle of NMR in unconventional environments and under suboptimal conditions (see Chapter 6).

While MRI provides solutions to many problems in industrial chemistry, the proper combination of methods and analysis is required, and some conditions regarding the feasibility and resolution of MRI can be given even a priori. This article summarizes the necessary background of NMR imaging and the parameters that usually enter into the image information or can be extracted from it at the control of the experimenter; only the very fundamentals of NMR itself are given, and the reader is otherwise referred to → Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy. It then provides a list of "fast" imaging methods (i.e., those that pass the test of routine use under realistic conditions) and puts a focus on the monitoring of transport processes, which are of particular interest to the field. Finally, some essential guidelines regarding the use of particular hardware and the feasibility of measuring certain substances are given.

2. Principles of Spatial Encoding in NMR

2.1. Repetition of NMR Facts

To understand and discuss NMR imaging, one can mostly avoid a full description of the origin of the NMR signal and its theoretical derivation, which would involve delving deeply into quantum mechanics. The argument for a substantial simplification of the problem lies to a certain degree in the statistical nature of the NMR effect itself: while the underlying resonance phenomena appear on a nuclear level and therefore must follow the particular rules of quantum mechanics, the output of an imaging experiment results from an averaging over a large number of spins or molecules, so that one can treat the system like an array of macroscopic magnetizations, such as a set of compass needles. Note, however, that certain fundamental effects, such as those due to mutual coupling of spins, are not reproduced in this framework, and the classical description must always be taken cum grano salis. For a deeper insight into the subject, the reader is referred to standard textbooks covering the theoretical background and general aspects [1 – 6], or in-depth discussions of NMR spectroscopy [7 – 13]. A broad, dictionary-style treatment of all topics can be found in [14, 15].

The principle of NMR itself, which is necessary to understand its extension to NMR imaging, can be summarized in just a few essential equations that describe the magnitude and time

dependence of the acquired signal. First of all, how large is the signal amplitude? When the spins of an arbitrary sample become polarized in a strong magnetic field $\boldsymbol{B}_0$, a net magnetization results which is parallel or antiparallel to $\boldsymbol{B}_0$. The value of this magnetization $\boldsymbol{M}_0$ is not the quantity usually measured; in fact, it is possible to determine it by detecting the force on a balance with the sample inside and outside of the magnetic field, but this datum is of very limited use. By far the majority of the information obtained in NMR stems from the time dependence of the magnetization which, once removed from equilibrium — for instance by rotating it into a direction perpendicular to the magnetic field, hereby employing a pulse of rf irradiation at the resonance frequency — precesses about $\boldsymbol{B}_0$ and returns to its equilibrium due to processes called *relaxation*. The precessing magnetization induces an a.c. voltage inside the receiver coil, wound perpendicular to $\boldsymbol{B}_0$. This voltage $U_{\mathrm{ind}}(t)$ is recorded, and both the frequency spectrum and the phase of the signal are extracted via Fourier transformations. The voltage is proportional to the time derivative of the magnetization

$$U_{\mathrm{ind}}(t) \propto \frac{\mathrm{d}\boldsymbol{M}(t)}{\mathrm{d}t} = \gamma\, \boldsymbol{M}(t) \times \boldsymbol{B}(t) \tag{1}$$

where subscripts have been removed to indicate that neither $\boldsymbol{B}$ nor $\boldsymbol{M}$ is, in general, an equilibrium and time-independent quantity, and γ is the gyromagnetic ratio specific for a given isotope. Neglecting relaxation for the moment, which leads to the eventual damping of the signal and describes the return to the spin system's equilibrium, the transverse (observable) fraction of the magnetization $\boldsymbol{M}_+(t)$ can be written as

$$\boldsymbol{M}_+(t) = \boldsymbol{M}_0(t) \exp(i\omega_0 t) \tag{2}$$

so that its time-derivative is proportional to the initial magnitude M_0 as well as to the precession frequency ω_0:

$$U_{\mathrm{ind}} \propto \frac{\mathrm{d}\boldsymbol{M}_+(t)}{\mathrm{d}t} \propto \boldsymbol{M}_0 \omega_0 \tag{3}$$

The first factor, the amplitude M_0, is given by Curie's law:

$$\boldsymbol{M}_0 = N \frac{\gamma^2 \hbar^2 I(I+1)}{3 k_{\mathrm{B}} T} \boldsymbol{B}_0, \tag{4}$$

where I is the nuclear spin quantum number (see below), $\hbar$ Planck's constant, k_{B} Boltzmann's constant, N the number of nuclei, and T the temperature. To maximize signal intensity, and therefore magnetization, one would thus want to work at a high magnetic field, use a sufficiently large sample, and detect nuclei with a large gyromagnetic ratio γ. Of all stable isotopes, the nucleus of the hydrogen atom ^{1}H has the largest γ. Furthermore, it is contained in all organic matter, and the ^{1}H isotope has almost 100 % natural abundance, which is the reason why the majority of imaging experiments is carried out with ^{1}H nuclei. However, imaging experiments have also been performed successfully on other isotopes, called "X nuclei" in the NMR language.

Curie's law describes a macroscopic magnetization, but its origin is found in the nuclear equivalent of the magnetization, the *spin*. This quantity resembles a compass needle which is located at the core of the nucleus; brought into a magnetic field, its energy state will depend on its orientation relative to the field direction. The spin is a quantum property, i.e., it can only assume quantized (half-integer or integer) values, given by the total spin quantum number: $I = 0$, 1/2, 1, ...

From this picture, the origin of both Curie's law and the resonance phenomenon can be derived. First, nuclei with different energy states will populate the respective levels in a statistical manner, obeying the Boltzmann distribution, which for two spin states +1/2, −1/2, reads:

$$\frac{n_{-\frac{1}{2}}}{n_{+\frac{1}{2}}} = \exp\left(-\frac{\hbar\omega_0}{k_{\mathrm{B}} T}\right) \tag{5}$$

If one inserts typical values for the magnetic field strength (say, 10 T) and room temperature (T = 298 K), the population difference turns out to be only a tiny fraction of 0.007 % for ^{1}H nuclei. This small bias is what provides the equilibrium value M_0.

In the above equation, the energy difference between the two levels is already expressed by its frequency equivalent $\Delta E = \hbar\omega_0$, where ω_0 is the Larmor frequency that denotes, for instance, the frequency of the rf irradiation that is used to induce transitions between levels and thus to manipulate the magnetization. At the same time, it describes the precession frequency of the magnetization about the direction of $\boldsymbol{B}_0$, giving rise to the induced voltage in the detector coil, as was mentioned above. The spin energy levels, and thus the Larmor frequency, are proportional

to the magnetic field strength, which is written in the simplest but most fundamental equation for NMR imaging:

$$\omega = \gamma |\boldsymbol{B}| \tag{6}$$

Because $\boldsymbol{B}$ is not just the externally applied field, but the magnetic field at the local position of the nucleus itself, which may vary from one nucleus to another, a wealth of information is included in the value of ω, or rather its spectral distribution. A large part of the toolbox of NMR is built around this simple dependence. Two regimes can be distinguished that provide entirely different information about the system:

The *microscopic regime* is given by the immediate vicinity of the nucleus. It is surrounded by electrons the motion of which — just like the motion of any electric charge — induces a magnetic field that shields the nucleus from the external field, resulting in the nucleus' specific local magnetic field. The single electron of the hydrogen atom shields a fraction of some 10^{-5} of the external field. Because the shielding depends on the actual charge distribution, which, in turn, is a consequence of the molecular environment of the hydrogen atom, a particular moiety can be identified by the shielding effect it has on the nucleus. From $\omega = \gamma \boldsymbol{B}$ we see that the resonance frequency of all nuclei varies proportionally to the field strength. The difference relative to a standard sample is called the *chemical shift* and is measured in unitless numbers, given as ppm (parts per million, 10^{-6}). Comparing all proton-containing chemical substances, the total range of ^{1}H nuclei resonance frequencies covers about 12 ppm. For instance, in an external magnetic field of 9.4 T, i.e., at a resonance frequency of 400 MHz, the maximum difference in frequencies observed is only about 4800 Hz. To distinguish subtle differences between molecules, the resolution of a good spectrometer must be much better; often values of 10^{-10} (i.e., 0.4 Hz in this example) can be reached (see → Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy).

The *macroscopic regime* is the one which is directly accessible by the magnet designer. By introducing, on purpose, an inhomogeneity into the magnetic field by means of additional coils, $\boldsymbol{B}$ and therefore ω are made functions of the position. Of course, this only makes sense if each value of the field $\boldsymbol{B}$ occurs only once in the entire sample volume, so that an unambiguous assignment of the position is possible. The most obvious solution is the generation of a linear field dependence. The relation between position and detected signal is introduced in Section 2.1.

Figure 1. Behavior of the magnetization in a simple echo experiment. Top: a free induction decay (FID) follows the first 90° pulse; x denotes the phase of the pulse, i.e., the axis about which the magnetization is effectively rotated. The 180° pulse is applied with the same phase; the echo appears at twice the separation between the two pulses and its phase is inverted to that of the initial FID. Bottom: the magnetization vector at five stages of the sequence drawn in a coordinate frame rotating at ω^0 about the z axis: before the 90° pulse, the magnetization is in equilibrium, i.e., parallel to the magnetic field (z); immediately after the 90° pulse, it has been rotated (by 90°) into the transverse (xy) plane; as it is composed of contributions from different parts of the sample, the slightly different local fields lead to a loss of coherence, i.e., to a free induction decay in the pick-up coil; before the 180° pulse, the different contributions (narrower arrows) have lost part or all of their coherence; after the 180° pulse, each partial magnetization has been flipped (by 180°) due to the effect of the electromagnetic field of the pulse, but still sees the same, slightly different local fields; at a time corresponding to twice the pulse spacing, the different phase shifts relative to the average value have been reverted, all partial magnetizations are in phase again, and their signal contributions add up coherently — a spin echo is generated.

However, before spatial encoding is described, the basic building block of an imaging experiment is explained by a simplified graphic representation of a basic NMR *pulse sequence*. The effect of either the microscopic or the macroscopic regime on the magnetization are visualized by the schematic picture given in Figure 1 that relates the behavior of the magnetization (the broad arrows in the sketches at the bottom) with the events that take place in

the transmitter/receiver unit of the spectrometer (top row). In the beginning, the *longitudinal magnetization* is in equilibrium and no signal is detected. The first rf pulse (called a 90° pulse since the pulse duration is just long enough to rotate the longitudinal magnetization by that angle) delivers $\boldsymbol{M}$ to the transverse plane and creates *transverse magnetization*. Here, the x in the subscript of 90° indicates a rotation about the x axis to place the transverse magnetization along the y direction. Immediately after such a 90° pulse, the magnetization still has its original magnitude but is forced to precess in the transverse plane about $\boldsymbol{B}_0$, inducing a signal in the receiver coil, the so-called *free-induction decay* (FID). The transverse magnetization (also called coherence) is the sum of many contributions, originating from different spin positions inside a molecule and from different regions in space. Both effects — which were separated into microscopic and macroscopic above — generate a certain spread of local fields $\boldsymbol{B}$, and of Larmor frequencies ω, so that the individual contributions of the initial (maximum) magnetization begin to "fan out" (note that the plot in Figure 1 must be understood as the *rotating frame*, i.e., one assumes a point of view that is rotating with the carrier frequency of the transmitting radio field about the z axis. In the rotating frame, some partial magnetizations (also called *isochromats*) precess faster, while others precess slower than the average. Eventually, their vectors add up to zero and no signal is detected in the receiver. The 180° pulse "flips" all isochromats around, so that the faster ones suddenly find themselves at the trailing edge, but because the physical reason for their precession frequency has not changed, they begin to catch up with the slower ones. This process goes completely unnoticed by the operator of the NMR spectrometer, because the isochromats remain in a decoherent state relative to each other, and their vectorial sum is still zero. Only after a time which is exactly twice the interval between the two rf pulses do they get in phase again, and in this moment, the broad arrow, the complete magnetization, is regained, but now in the direction opposite to where it had pointed to immediately after the first rf pulse. This is because the 180° rotation was performed about the x axis, as depicted in Figure 1. By changing the *phase* of the rf pulses, i.e., by changing the axis about which the rotation of the magnetization vector takes place, as discussed above, the final direction of this arrow can be chosen at will. The recovered magnetization is the so-called *spin echo*. The second half of this echo is identical to the FID at the beginning of the sequence, apart from the actual signal amplitude, which has decreased due to microscopic or macroscopic processes that have happened in the system during the time between the FID and echo acquisition. Comparing echo and FID amplitudes can give a first starting point for analyzing dynamics that are taking place in the sample; using the echo and continuing the procedure by applying more rf pulses allows one to recycle the very same magnetization many times and extract even more information from its behavior. Imaging is achieved by appropriate manipulation of the magnetization in the intervals between the rf pulses.

2.2. k Space

The encoding of positional information into the NMR signal, and the various experimental schemes that allow this encoding in an optimized way to match the needs of the desired study, are frequently discussed in terms of *k space*. This concept has been borrowed from scattering experiments (light, X-ray, neutron scattering) where the structure of matter is revealed by interactions with the wave nature of incoming radiation, a function of their *wavelength* or, in accordance with the structure of the scattering pattern, its reciprocal, the *wave vector* or $\boldsymbol{k}$ *vector*. Note that in NMR imaging, it is not the wave vector of the rf irradiation itself, but rather a spatially periodic dependence of the magnetization that is generated by a suitable manipulation of the spin system in the presence of a spatially dependent magnetic field. The actual image information, i.e., the distribution of magnetization in real space $\boldsymbol{r}$, can be obtained from a Fourier transformation of the signal in dependence on the reciprocal vector $\boldsymbol{k}$. Because of this fundamental relationship, it appears worthwhile to gain some elementary understanding about magnetization encoding in k space.

The spatial dependence of the NMR signal is introduced straightforwardly by allowing the magnetic field strength in Equation 6 to become dependent on position $\boldsymbol{r}$:

$$\omega(\boldsymbol{r}) = \gamma\,|\boldsymbol{B}(\boldsymbol{r})| = \gamma(|\boldsymbol{B}_0| + \boldsymbol{g}\cdot\boldsymbol{r}) \tag{7}$$

Here, the magnetic field strength has been split into a homogeneous part $\boldsymbol{B}_0$ and a spatially dependent part, expressed by the first derivative of the magnetic field strength, the gradient vector $\boldsymbol{g}$, which renders the resonance frequency proportional to the position of the spin $\boldsymbol{r}$. This expression resembles the conditions of a typical MRI setup, where the additional, spatially varying field $\boldsymbol{g}\,\boldsymbol{r}$ is only a small correction to $\boldsymbol{B}_0$. Strictly speaking, the gradient has the properties of a 3×3 tensor because the derivatives of all three orthogonal components of $\boldsymbol{B}$ must be computed. However, $\boldsymbol{B}$ is usually taken as pointing in the z direction, and its x/y components are negligible just like their spatial derivatives. Note that the product $\boldsymbol{g}\,\boldsymbol{r}$ indicates that only those components of the position vector which are parallel to the gradient direction possess a different resonance frequency.

Equation 7 expresses the Larmor frequency for a subset of spins at position $\boldsymbol{r}$. In an actual experiment with the purpose of generating an image of an extended object, a large number of these subsets, or *isochromats*, will give rise to a superposition of frequencies $\omega(\boldsymbol{r})$, weighted by the distribution of spins in the object. This distribution can formally be written by the density function of position: $\varrho(\boldsymbol{r})$. Since most NMR experiments consist of an initial rf pulse followed by one or more encoding periods with different properties, the signal detected at the end of such a sequence that includes a magnetic field gradient will contain a superposition of the spatial information that cannot be directly translated into an image. In order to generate the image of the object, one must modify the weighting function (the effective gradient $\boldsymbol{g}$ turned on during the time t, hence $\boldsymbol{g}t$) and record the signal for each weighting function separately, before reconstructing the actual spin density distribution. This approach corresponds to the scattering experiment with an incoming wave of vector $\boldsymbol{k}$. However, there is no direct NMR equivalent for a two-dimensional detector that allows, for instance, an X-ray diffraction pattern to be recorded in one shot. The values of the $\boldsymbol{k}$ vector rather must be set one by one and the NMR response signal acquired separately. [Note that Eq. 7 implies that there is a direct proportionality between the spin density distribution $\varrho(\boldsymbol{r})$ and the frequency distribution $\varrho[\omega(\boldsymbol{r})]$, which allows reconstruction of the projection of the spin density parallel to the direction of the gradient $\boldsymbol{g}$ if the latter is applied during data acquisition; this particular method is discussed in Section 2.3]

On the other hand, there is one major difference which makes NMR a particularly strong tool for investigating matter: unlike the classical scattering techniques, which only provide an intensity measure as their result, the NMR information is a complex number and also contains the phase of the signal (proper synchronization and detection of the induced voltage in quadrature allow the determination of the signal phase at any instant during acquisition). By applying field gradient pulses, the position can be encoded into the phase of the signal as a function of $\boldsymbol{k}$, while its magnitude and frequency remain available for assigning other information (see Sections 2.4, and 3.3).

Figure 2. Effect of a pulsed magnetic field gradient of strength $\boldsymbol{g}$ on the phase of a signal contribution originating from spins at position $\boldsymbol{r}$. Prior to the gradient pulse, all spins experience the constant magnetic field B0 and thus have the same Larmor frequency; the phase shift relative to this average value is zero. During the gradient pulse, the field becomes position-dependent and a phase shift ϕ is accumulated that is proportional to position $\boldsymbol{r}$ and time t. After the gradient pulse (i.e., after completion of the phase-encoding step), the spins memorize their individual phase shift? $\phi(\boldsymbol{r}) = \gamma\,\boldsymbol{g}\boldsymbol{r}\delta$.

Figure 2 demonstrates the effect of a linear field dependence that is introduced in the form of a constant gradient $\boldsymbol{g}$ which is applied only during a certain interval δ. This is called a — hence the frequently used term "pulsed field gradient (PFG) NMR" — and it can be of arbitrary shape, but a rectangle with sharp edges is often used and facilitates the discussion. The Larmor frequency is then simply switched between its value in the homogeneous field, $\boldsymbol{B} = \boldsymbol{B}_0$, $\omega_0 = \gamma\boldsymbol{B}_0$, before and after the gradient pulse, and the position-dependent value $\omega(\boldsymbol{r}) = \gamma\,|\boldsymbol{B}(\boldsymbol{r})| = \gamma(|\boldsymbol{B}_0| + \boldsymbol{g}\cdot\boldsymbol{r})$ during the gradient pulse. It is convenient to subtract the reference value, given

by the "average" field $\omega_0 = \gamma \boldsymbol{B}_0$ so that one obtains the frequency difference relative to an (arbitrarily chosen) position $\boldsymbol{r} = 0$:

$$\omega(\boldsymbol{r}) - \omega_0 = \gamma \boldsymbol{g} \cdot \boldsymbol{r}. \tag{8}$$

In NMR, data acquisition is demodulated with the carrier frequency corresponding to the magnetic field strength in use ω_{rf}, which is chosen usually close to ω_0, so that the frequency difference of Equation 8 can even be detected directly (see Section 2.2).

The bottom line in Figure 2 represents the phase ϕ of the signal, which in the rotating frame of reference is defined as zero in a homogeneous magnetic field. As soon as the gradient $\boldsymbol{g}$ is switched on, the phase angle grows linearly with time, according to $\phi(\boldsymbol{r}) = (\omega(\boldsymbol{r}) - \omega_0)t$. Because of the dependence of the Larmor frequency on position $\boldsymbol{r}$, this phase angle also depends on the position. After the gradient pulse is switched off, the difference in frequencies has led to an accumulated phase shift $\phi(\boldsymbol{r}) = (\omega(\boldsymbol{r}) - \omega_0)\delta$ with respect to the reference, and this will not change as long as the magnetic field remains homogeneous. Thus, the resulting phase shift of spins at position $\boldsymbol{r}$ following a gradient pulse of duration δ and strength $\boldsymbol{g}$ can be written as

$$\phi(\boldsymbol{r}) = \gamma\, \boldsymbol{g} \cdot \boldsymbol{r}\, \delta. \tag{9}$$

Since the signal generated by the precessing magnetization is a complex number, the phase shift created by this gradient pulse leads to an NMR signal which is the multiplication of the unperturbed NMR signal with the phase factor $\exp[i\phi(\boldsymbol{r})]$. To compute the total signal arising from all spins within the sample with a spin density distribution $\varrho(\boldsymbol{r})$, the different phase factors must be integrated over the entire volume:

$$\begin{aligned} S(\boldsymbol{k}) &= \int \varrho(\boldsymbol{r}) \exp[i\phi(\boldsymbol{r})]\, \mathrm{d}\boldsymbol{r} \\ &= \int \varrho(\boldsymbol{r}) \exp[i\gamma \boldsymbol{g} \cdot \boldsymbol{r} \delta]\mathrm{d}\boldsymbol{r} \\ &= \int \varrho(\boldsymbol{r}) \exp[i2\pi \boldsymbol{k} \cdot \boldsymbol{r}]\mathrm{d}\boldsymbol{r}. \end{aligned} \tag{10}$$

In this equation, the substitution $k = \frac{1}{2\pi}\gamma g \delta$ has been made to introduce the Fourier conjugate variable to $\boldsymbol{r}$. This is because Equation 10 formally is a Fourier transformation. The shape of the sample $\varrho(\boldsymbol{r})$ is the relation that is sought-after, and it can be derived by applying the inverse Fourier transformation to the signal function $S(\boldsymbol{k})$:

$$\varrho(\boldsymbol{r}) = \int S(\boldsymbol{k}) \exp[-i2\pi \boldsymbol{k} \cdot \boldsymbol{r}]\mathrm{d}\boldsymbol{k} \tag{11}$$

2.3. Phase Encoding and Frequency Encoding

Equation 11 constitutes the fundamental relationship for NMR imaging: in order to find the one-dimensional spin density $\varrho(\boldsymbol{r})$, one must determine the signal as a function of the wave vector $S(\boldsymbol{k})$.

For a proper application of the inverse Fourier transformation, $S(\boldsymbol{k})$ needs to be known as a continuous function. In practice, it is the fast Fourier transform (FFT) which is performed rather than the full, analytical Fourier transform, so that the sampling of $\boldsymbol{k}$ space at discrete, equidistant steps (typically 32, 64, 128) is performed.

The recipe for the first building block of NMR imaging, *phase encoding*, thus looks like this: apply a phase gradient of effective area $\boldsymbol{k}$, acquire the signal $S(\boldsymbol{k})$, repeat for a number of different equidistant values of $\boldsymbol{k}$, and perform the inverse Fourier transformation to reconstruct the spin density function of the sample $\varrho(\boldsymbol{r})$. The variation of gradients is symbolized by a diagonal line in Figure 3. In principle, the pulsed gradient can be applied at arbitrary times between the rf pulses.

Figure 3. Phase-encoding scheme in one dimension. A magnetic field gradient pulse is applied and is varied between subsequent scans (symbolized by the diagonal line). The actual timing of the gradient is arbitrary as long as it is placed between the rf pulses and before the acquisition of the echo signal.

Note that variation of the phase encoding gradient along one direction, say k_x, allows the reconstruction of the profile only in this direction, $\varrho(x)$. An example of this is shown in Figure 4, where the projection of a cylindrical object (such as a test tube filled with water) is depicted with the aid of simulated data. A series of FIDs is drawn in succession, a usual way of saving the data in a single, long vector file in which each FID is being acquired in the presence of a particular gradient value, so that the range $-k_{x,\max} \ldots k_{x,\max}$ is covered and $k_x = 0$ is in the center,

Figure 4. Simulated NMR data from a cylindrical object projected onto a direction perpendicular to the cylinder axis. Left: 128 steps of k_x were applied and the succession of FIDs plotted; $\boldsymbol{k}$ space is covered sufficiently well, i.e., the signal has decayed to zero at the largest values of k_x. The Fourier transform of the series of FIDs (taken from the first points or from the integrals over each FID) is a satisfactory representation of the projection of the sample shape. Right: only the central 32 k_x values were acquired; the Fourier transform suffers from bad resolution, but also from a nonvanishing baseline because the signal at the largest k_x values had not vanished.

giving maximum signal intensity. Figure 4 also demonstrates the effect of an insufficient coverage of $\boldsymbol{k}$ space on the image quality: if at the largest used value of k_x, the signal has not yet vanished, cutoff artefacts arise in the image (see Section 2.6).

The foremost advantage of phase encoding is the fact that the signal is acquired in the presence of a homogeneous magnetic field; the signal thus contains the full spectroscopic information, and this can be exploited to generate an image with individual spectra contained in each voxel representing the local chemical environment. This is one of the most powerful assets of NMR imaging. In one important example, an inhomogeneous distribution of a mixture of liquids can be imaged while obtaining the full spectroscopic dimension to distinguish the different phases and/or chemical species in the mixture. By this means, chemically selective, spatially resolved monitoring can be employed to study complex mixtures. The disadvantage of phase encoding is its inherent slowness: the signal function at each discrete value of $\boldsymbol{k}$ must be acquired separately, and a sufficient waiting time introduced to allow the magnetization to relax back to equilibrium (see Chap. 4 for strategies to reduce this waiting period).

One way out of this dilemma is the so-called *frequency encoding* technique. It is often referred to as an approach which is quite different from phase encoding, but in fact it is only the timing of $\boldsymbol{k}$ space sampling which is modified: in frequency encoding, the signal is acquired while the field gradient is present (see Fig. 5); it is then referred to as a *read gradient*. Equation 9 is still valid, so that each subsequent point of acquisition at a given time t is subject to the effect of a longer read-gradient field and thus contains a different distribution of phase angles. The full acquisition of one line in $\boldsymbol{k}$ space takes only a few milliseconds; Fourier transformation of this signal $S(\boldsymbol{k})$ again yields the profile of the object in the corresponding direction $\varrho(\boldsymbol{r})$, so that Equation 11 also maintains its validity. Since in frequency encoding the time t is varied at constant gradient strength, it is also possible to write the signal of the frequency encoding technique

as $S(t)$, and its Fourier transformation directly renders the frequency distribution of spins in the sample. Because of $\omega = \gamma \boldsymbol{gr}$, this frequency distribution is proportional to the spin density distribution of the object. The difference in the *phase encoding* method is that the signal is acquired after it was exposed to a gradient field of duration δ and strength $\boldsymbol{g}$. Usually, the gradient strength $\boldsymbol{g}$ is varied, and for each such step a new signal is utilized, formed either by excitation or echo formation.

Figure 5. Demonstration of the formal equivalence of phase encoding and frequency encoding. Phase encoding (top): the gradient of duration δ and strength $g_{\max}$ is split into eight equal steps Δg. The signal is acquired n times (here: $n = 8$), following a gradient of strength $i\Delta g$ where i is varied from 1 to n. Frequency encoding (bottom): the gradient strength $g_{\max}$ is maintained but the total duration δ is split into eight equal steps Δt. The signal is acquired n times (here: $n = 8$), following a gradient of duration $i\Delta t$ where i is varied from 1 to n. In both cases, the signal corresponding to the same $n = 8k$ values between zero and $k_{\max}$ is sampled, where $k_{\max} = (2\pi)^{-1}\gamma g_{\max}\delta$.

While frequency encoding saves time because it samples one dimension in $\boldsymbol{k}$ space in a single acquisition, its disadvantage is that the spectral information of the spin system is masked by the spatial encoding; the result is a superposition of chemical shift and positional information. In other words, an object filled with a substance that has a spectrum consisting of two lines will render a double image because the physical reason for the frequency shift cannot be separated straightforwardly. However, often substances with simple spectra such as water are considered, or the separation between different spectral lines is negligibly small. Under such conditions, frequency encoding is often the method of choice.

2.4. Slice Selection

In many real studies, a cross-sectional image of an object contains all the necessary information that the researcher is interested in. Sometimes it might even be desirable to generate an image of only a partial volume of the object, or to determine a spectrum at a particular position. However, the methods discussed so far affect all spins within the volume that is common to the gradient coil unit and the resonator coil, and do not focus on a partial volume. Volume selection, or more generally *slice selection*, is indeed possible; again, it exploits the fundamental relation $\omega = \gamma \boldsymbol{B}$, but in a slightly different sense. Up to now, it has been implicitly assumed that all rf pulses in the imaging sequences affect all spins in the same way. This is strictly true only for a *hard pulse*, i.e., a pulse with a bandwidth well exceeding the range of Larmor frequencies in the sample. The bandwidth of an rf pulse is approximately given by the reciprocal of its duration: a short pulse has a broad frequency spectrum. More precisely, the frequency spectrum of an rf excitation is the Fourier transform of its shape function. But because of $\omega(r) - \omega_0 = \gamma \boldsymbol{g} \cdot \boldsymbol{r}$, frequency is proportional to position if a magnetic field gradient $\boldsymbol{g}$ is present. In principle, a slice of arbitrary shape can be excited if the pulse is modulated by a function which is the inverse Fourier transformation of the shape. A volume is likewise excited by combining rf pulses and orthogonal gradients, and even arbitrary shapes can be selected [16]. For the most appropriate excitation profile, a rectangular slice, this is particularly simple — the Fourier transform of a rectangle is the sinc function, $\sin x/x$ (see Fig. 6). Generating an rf pulse of the proper length which is modulated by a sinc function will thus excite a rectangular slice of the sample and leave the remaining spins unaffected. In practice, the function is cut at a certain number of periods to limit its duration, and this results in a somewhat imperfect shape of the slice, which is usually tolerated (see Fig. 6). In typical imaging, the *shaped pulse* or *soft pulse* has a duration on the order of milliseconds, compared to the *hard pulse* of some tens of microseconds. The terms "hard" and "soft" can thus also be understood in the sense of the power level of the pulses, which necessarily is much higher if a very short

Figure 6. Soft rf pulses (left) in the shape of a sinc (sin x/x) function, and their Fourier transforms (right), equivalent to the excited slice in the presence of a constant magnetic field gradient. The well-defined sinc function (top) produces a slice excitation that deviates only slightly from a perfect rectangle. A cutoff sinc function, such as that shown in the bottom part of the figure, produces a distorted slice profile which is, however, often sufficient for slice selection in multidimensional imaging.

pulse has to achieve the same 90° rotation of the magnetization.

The shape of any rf pulse can be chosen in such a way that the excitation profile is a rectangular slice. In the light of experimental restrictions, which often ask for pulses as short as possible, the slice shape will never be perfect and also depends on the pulse's flip angle. For instance, the commonly used 90° pulse is still acceptable, while a 180° pulse produces a good profile only if it is used as a refocusing pulse, but not when it is supposed to act on the longitudinal component of the magnetization M_z. Sometimes, pulses of even smaller flip angles are used that provide a better slice selection (for a discussion of imaging with small flip angles, see Section 4.2.

2.5. 2D and 3D Imaging

Obtaining two- or three-dimensional NMR images is achieved by employing different combinations of the aforementioned techniques. For instance, pure phase encoding is extended straightforwardly from the simple module shown in Figure 3, the only requirement being that all gradient pulses are stepped independently of each other, and are applied either simultaneously or in series. Equation 11 already contains this possibility since $\boldsymbol{r}$ and $\boldsymbol{k}$ are written as vectors; however, in Equation 12 the three orthogonal components are split and — for the sake of clarity — the same relation is expressed by a threefold integral to highlight the three-dimensional nature of the experiment:

$$\varrho(x,y,z) = \int\int\int S(k_x,k_y,k_z)\exp[-i2\pi k_x x]\exp[-i2\pi k_y y] \cdot\exp[-i2\pi k_z z]\mathrm{d}k_x\mathrm{d}k_y\mathrm{d}k_z \quad (12)$$

The disadvantage of long experimental times in phase encoding becomes almost prohibitive for 3D experiments: to generate a three-dimensional image with a satisfactory resolution of, say, 64 × 64 × 64 points, an equivalent number of 64^3 individual signals must be acquired. Assuming a repetition time of 1 s between acquisitions, this corresponds to an experimental time of three days.

Equation 12, however, allows one of the three dimensions to be scanned by frequency encod-

ing. This has turned a combination of frequency encoding in one dimension and phase encoding in one or two further dimensions into one of the most widespread imaging techniques. Figure 7 gives a schematic example of a suitable pulse sequence, where the succession of gradients is arbitrary as long as all phase encoding steps are completed before the beginning of signal acquisition.

Figure 7. Schematic plot of a basic three-dimensional imaging pulse sequence with frequency encoding along one axis (read), and phase encoding along the two remaining orthogonal directions. The choice of directions is arbitrary, as is the position of the phase gradients within the sequence.

Reconstruction of a two- or even three-dimensional spin density distribution by employing only frequency encoding is possible by varying the direction of the gradient by rotation of the sample or the gradient coil, or by rotating the gradient fields by appropriate combinations of g_x, g_y, and g_z gradients. The technique is known as *backprojection/reconstruction* and is similar to image processing routines used for generating 3D X-ray images in computer tomography (CT). While the advantage is that a crude picture of the sample can be obtained right away long before image acquisition is completed, some disadvantages are the lower signal-to-noise ratio, resolution, and image quality, and that it does not allow the assignment of spectral features in the object. The reason for these compromises is related to the fact that the image function $\varrho(\boldsymbol{r})$ is extracted by an algorithm different from the inverse Fourier transformation.

By using all three building blocks of phase encoding, frequency encoding, and slice selection, a very common NMR imaging sequence can be constructed which is routinely employed for acquiring slices of an extended object (see Fig. 8). It consists of a slice-selection gradient in one direction, a frequency gradient in a second, and a phase-encoding gradient in the third direction. The directions are orthogonal to each other and their order is arbitrary, hence the usual labeling with "read, phase, slice" instead of "x, y, z".

Figure 8. Typical basic three-dimensional imaging sequence with slice selection, frequency encoding, and phase encoding in three orthogonal directions. The compensating lobe for the read gradient is drawn as a rectangle with negative intensity directly before the actual read gradient. The shape of the 180° rf pulse is drawn schematically to indicate that a soft pulse is used.

A final but important comment must be added to the discussion of the sequence in Figure 8. The read gradient is preceded by a negative lobe of half its area. The reason for this is that one wants to scan the whole $\boldsymbol{k}$ space dimension with the read gradient. If one switched on the gradient and began acquisition immediately, the first acquired point would represent $\boldsymbol{k} = 0$ and only positive values of $\boldsymbol{k}$ would be scanned. By applying a negative lobe before acquisition, the origin is moved toward a negative value before acquisition is begun; applying a lobe with half of the negative area of the read gradient means that the condition $\boldsymbol{k} = 0$ appears at the center of the acquisition window. The timing of the sequence is such that also the echo generated by the rf pulses appears in this instance. It is called *spin echo* and refocuses the effect of constant background gradients, but also the spread in ω brought about by the properties of the sample spectrum (see also discussion of Fig. 1). The combination of negative and positive lobes of g_{read} also produces an echo, the *gradient echo*. It appears at the point in time when $\boldsymbol{k} = 0$, or, in other words, when $\int g_{\mathrm{read}} \mathrm{d}t = 0$, i.e., the total effect of all gradients in the read direction vanishes. The integral is the mathematical definition of the area of the gradient, or the zeroth moment of the gradient $\boldsymbol{m}_0$. The general nomenclature will be put to use in Section 5.2.

The equivalence of phase encoding and frequency encoding is best seen in relating k space and r space to each other, which is visualized for the two-dimensional case in Figure 9. The only essential feature is the equidistant scanning of points in k space, indicated by a rectangular grid, which generates an image in r space of likewise equidistant points. The separation between points needs not be the same in both directions, the order of acquisition is – at least in principle – arbitrary, and each point can be part of a phase- or frequency-encoding scheme.

Figure 9. Scanning of 2D k space and the equivalent reconstruction in 2D r (position) space. In this example, the same number of points is sampled in k_x and k_y directions, but the total range of k_y values is 50 % wider; as a consequence, the image resolution along y is 50 % better than along x, while the imaging window along y (field of view, FOV) is reduced by the same amount.

2.6. Spatial Resolution

To demonstrate how the Fourier relation works, Figure 10 shows how a two-dimensional object — a letter "i" in a circle — would look like in an NMR image, that is, its spin density function $\varrho(x,y)$ is shown, and the original signal function which is obtained by varying $\boldsymbol{k}$, $S(k_x, k_y)$. While $S(k_x, k_y)$ is a complex function, only its real part is plotted. Because of the reciprocal relationship between $\boldsymbol{r}$ and $\boldsymbol{k}$, one can roughly say that the signal of high intensity in the vicinity of $\boldsymbol{k} = 0$ contains information about the general shape of the sample, and the small contributions at large $\boldsymbol{k}$ values are responsible for the fine structure, i.e., the resolution of the image. Although this is an oversimplified view, it is often helpful to keep this inverse relationship in mind and to estimate which effect the distortion of a particular part of the $\boldsymbol{k}$ space data will have on the $\boldsymbol{r}$ space image. In principle, only an analytical Fourier transformation of a continuous signal function $S(\boldsymbol{k})$ renders a perfect result; the compromise of a finite sampling of $\boldsymbol{k}$ space gives rise to imperfections in the NMR image, which arise in addition to potential technical shortcomings such as hardware limitations or noise.

The choice of gradient strength and duration can be optimized if the size of the object is known. From Equations 9 and 10 it becomes clear that too large a gradient will lead to an ambiguous assignment of positions if the maximum phase angle exceeds 2π. One must therefore make sure that the difference between phase shifts generated for spins at the extreme ends of the sample is smaller than 2π for each different value of the gradient. In other words, $2\pi > 2(\gamma g_{\max}\delta r_{\max})/(n-1)$ if the gradient is varied in the range $-g_{\max} \ldots + g_{\max}$ in n steps. The coverage in $\boldsymbol{r}$ space achieved with a particular set of gradient values is called the field of view (FOV) and is obtained from

$$\mathrm{FOV} = \frac{n-1}{2}\,\frac{2\pi}{\gamma g_{\max}\delta} \tag{13}$$

For n gradient steps (n different k values), the image function $\varrho(r)$ also possesses a resolution of n points as a consequence of the FFT procedure. Naturally, a larger $g_{\max}$ results in a better resolution if the number of steps n is chosen in such a way that the FOV slightly exceeds the object size itself (see Fig. 9). Note that choosing too small a field of view will lead to so-called aliasing, i.e., those picture elements that correspond to a phase shift that exceeds the range $\pm\pi$, will appear at the other side of the image, so that superposition of two or more signal contributions into the image (backfolding) can occur. Note that Equation 13 is again valid for phase encoding and frequency encoding alike; in the latter case, n is the number of time points during acquisition in the presence of the magnetic field gradient.

A much more detailed introduction to the basics of NMR imaging can be found in a number of textbooks and monographs [17 – 20]. These also cover most of the aspects presented throughout the following chapters. While [21, 22] are dedicated to the multitude of pulse sequences used for MRI, [23, 24] provide a collection of

Figure 10. Two-dimensional objects in position space (top row) and their Fourier transform, corresponding to the shape of the signal function $S(k_x,k_y)$ (bottom row). The actual object, a letter "i" inside a circle, is shown as the sum of three individual objects. Likewise, the Fourier transform is additive and the signal functions corresponding to each of the objects are shown for comparison.

applications from different, mostly nonmedical fields of research.

3. Image Contrast

3.1. Relaxation

At first sight, the image brightness appears to be a direct measure of NMR signal intensity obtained under the particular pulse sequence used in image acquisition, which intuitively is considered to be the number density of spins, e.g., of protons in the sample. However, this brightness does not only reflect spin density, but is weighted by the chemical constitution, hardness or softness of the material, diffusion coefficient, translational motion, or molecular motion on a much faster timescale, which actually defines the contrast of an image. The contrast highlights the heterogeneity of the sample with respect to the chemical and physical properties mentioned. This is because these properties reflect on NMR parameters such as NMR signal amplitude, frequency, T_1 and T_2 relaxation times, and line shape. One can learn much more about the properties of a sample since the NMR imaging sequence can be designed accordingly to obtain the desired contrast. The wide range of contrast that can be imposed on a spin-density image is the unique strength of NMR imaging. On the other hand, quantitative NMR imaging, i.e., the determination of local spin densities and therefore substance concentrations, is not straightforward because of these manifold influences, and some care must be taken to derive the spin density distribution in an object.

The most obvious influence on image contrast is given by the relaxation parameters, in particular the spin – lattice relaxation time T_1 and the spin – spin relaxation time T_2. Both describe the return of the magnetization to its equilibrium value which is determined by the strength and direction of the external magnetic field. Considering that any encoding of information requires the manipulation of the magnetization that removes it from its equilibrium, one can conclude that full relaxation removes the memory about any previous encoding events and is the requirement for performing a new experiment. Imaging sequences such as those drawn in Figures 3, 7, and 8 can then be repeated only with sufficient waiting times in between. Incomplete relaxation, on the other hand, implies that the spin system potentially carries information from previous encoding steps. This can either be a nuisance or an advantage, as will be demonstrated in Chapter 4. In any case, incomplete relaxation reduces the signal intensity and therefore the image brightness compared to the ideal, fully relaxed state.

Historically, relaxation effects were introduced phenomenologically by amending the Bloch equation, i.e., the equation describing the time dependence of the magnetization vector (Eq. 1), by a decaying term:

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = \gamma \boldsymbol{M} \times \boldsymbol{B} - \mathbf{R}(\boldsymbol{M} - \boldsymbol{M}_0) \tag{14}$$

Here, $\mathbf{R}$ denotes the relaxation matrix that has the diagonal elements $R_{xx} = R_{yy} = 1/T_2$, $R_{zz} = 1/T_1$. Putting Equation 14 in words, the transverse magnetization M_x will decay from its initial value to zero with a time constant T_2, while at the same time the longitudinal component M_z returns to its equilibrium value M_0, with a time constant T_1. The definition of these time con-

stants is based on the assumption that the relaxation process follows an exponential behavior. This is often the case, but not always; if a different time dependence is found, the relaxation time loses its meaning in the stricter sense. It is then formally replaced by a function that can be split into a sum of many exponentially decaying functions, or a different measure is used; for practical reasons, the time during which the magnetization decays to e^{-1} of its initial value is often simply called the relaxation time T_1 or T_2.

The theory of relaxation is covered in most standard introductory books, e.g., [1 – 6], and is not repeated here. In principle, relaxation processes are determined by the interaction between spins. This is usually the dipolar coupling in the case of protons, but other types of interactions can also contribute significantly. Once the spin system is brought out of equilibrium by an rf pulse, it begins to return to the initial state, i.e., the populations of the energy levels will return to the Boltzmann distribution of Equation 5. This is only possible if energy is exchanged between neighboring spins, and an energy exchange generally requires a change of orientations, and therefore motion. Transverse relaxation happens simultaneously, but is somewhat different since it is described by a loss of coherence of magnetization, which does not necessarily require a change of the total energy. Because of the additional mechanisms leading to this coherence loss, T_2 is often shorter than T_1. The T_2^* relaxation time is *not* an intrinsic property of the material itself and is called the effective transverse relaxation time. Inhomogeneity in static magnetic fields and the sample's magnetization due to susceptibility variations are the cause for T_2^* and the resulting coherence loss is reversible, while the true T_2 describes an irreversible decay process. T_2^* is generally shorter than T_2 and often becomes important in imaging experiments where a "perfect" magnetic field cannot be achieved. It is then the time constant that describes the free induction decay, but the lost coherence can be recovered at the center of a spin echo, as is drawn schematically in Figure 1. The effect of relaxation can be demonstrated with the help of Figure 11 and Equations 10 and 12.

Figure 11. Schematic plot of a basic two-dimensional imaging sequence with relaxation effects. During the encoding period, the magnetization remains in the transverse (xy) plane and decays by a factor $\exp(-\mathrm{TE}/\mathrm{T}_2)$, where TE is the echo time. After signal acquisition, which occurs at the time of the echo, the sequence is repeated following a waiting time TR (repetition time), during which the longitudinal magnetization approaches its equilibrium exponentially according to $[1-\exp(-\mathrm{TR}/\mathrm{T}_1)]$.

It is sufficient to remember that the components of the magnetization in the transverse plane, M_x and M_y, experience T_2 and T_2^* relaxation, while the component parallel to the magnetic field M_z approaches its equilibrium with T_1. The correct expression for the signal intensity can then be rewritten as:

$$S\,(k_x,k_y,k_z) = \int\!\!\int\!\!\int \varrho\,(x,y,z)\ \exp\left[-\mathrm{TE}/T_2\,(x,y,z)\right] \left(1-\exp\left[-\mathrm{TR}/T_1\,(x,y,z)\right]\right) \exp\left[i2\pi k_x x\right]\ \exp\left[i2\pi k_y y\right] \exp\left[i2\pi k_z z\right] \mathrm{d}k_x\,\mathrm{d}k_y\,\mathrm{d}k_z \tag{15}$$

This equation assumes the general case where the parameters T_2 and T_1 depend on position, which is often the case, in particular if the material composition in an object is heterogeneous. Under these circumstances, the actual spin density $\varrho(x,y,z)$ will be damped by a position-dependent factor. Without knowledge of the dependence of $T_1(x,y,z)$ and $T_2(x,y,z)$, which is generally not given, the spin density cannot be retrieved unless the conditions $\mathrm{TE} \ll T_2$ and $\mathrm{TR} \gg T_1$ are met for the whole range of relaxation times in the sample. These two time intervals are called "echo time" (TE) and "repetition time" (TR) where the nomenclature is borrowed from medical imaging.

Figure 12. . Images of a human brain with T_1 weighting (left) and T_2 weighting (right). T1 weighting is brought about by using a TR that is short relative to the average T_1 of the tissue. Gray matter has a slightly longer T_1 relaxation time than white matter, making it appear darker in the image; the contrast depends also on the field strength used. T_2 weighting is achieved by employing a long TE. Water or, more generally, free liquid has a long T_2 and appears bright. The major potential of medical relaxation weighted imaging is in the detection of lesions and cancerous tissue, which contains more water and therefore usually has longer relaxation times. (Reproduced from http://www.thebraincentre.org/neuroradiology/mri/image/mri03.jpg, The Brain Center, Canossa Hospital, Hong Kong.)

An example where different repetition and echo times lead to different contrast is shown in Figure 12.

One of the first criteria for determining the feasibility of a particular imaging experiment is a good estimate for the relaxation times of the system under study, which then must be compared with the times required for executing the pulse sequence, frequently determined by hardware limitations (see Chap. 6). In bulk water and most organic liquids, one usually has $T_1 = T_2$ and both are in the range of several seconds. This is sufficiently long for executing all types of imaging pulse sequences, but might have the disadvantage that repetition times become prohibitively long, or alternatively the image is always T_1-weighted. The addition of soluble salts that form a hydration shell can help, because the extra relaxation mechanism introduced by the ions can reduce the relaxation times by orders of magnitude [25, 26]. Such salts are employed as contrast agents in routine medical MRI, and their design towards an increased specificity currently represents a dynamic research area [27].

However, for liquids with a high concentration of ions, or very viscous liquids, the opposite problem can arise if the relaxation times become too short for completing a full pulse sequence and to acquire the remaining signal. The extreme case is represented by solids, which have a very long longitudinal relaxation time T_1 (anything from seconds to hours, depending on the rigidity and order of the molecular structure), while the transverse relaxation time T_2 becomes very short, often being only on the order of 10 µs. To a lesser degree, this also happens if liquids are in contact with large specific interfaces which can act as additional relaxation sources. In an important example, this is exploited for getting information about the pore structure for liquids in porous media [28].

3.2. Diffusion

While relaxation is sensitive to mobility on a molecular scale and is influenced by a combination of effects of the immediate molecular environment, the diffusion coefficient directly describes the translational motion of fluids. In liquids it is approximately inversely proportional to the bulk viscosity, but is reduced if geometrical restrictions exist. In a pulsed-field gradient NMR experiment, the self-diffusion coefficient D is not determined directly, but the mean-square displacement of the spins, which is related, in turn, to the diffusion coefficient by Einstein's equation:

$$<\boldsymbol{r}^2> = 2d\,D\Delta \tag{16}$$

Figure 13. Diffusion-weighted images of three liquids with different self-diffusion coefficients. As the strength of the bipolar gradient is increased from left to right, the signal from the liquid with the largest diffusion coefficient (in this case, water) decays fastest. The initial image represents the ^{1}H spin density of the liquids. (Reproduced with permission from U. Scheler, Leibniz Institute for Polymer Research Dresden.)

Here, Δ is the time used for the encoding which is achieved by a bipolar gradient applied during a pulse sequence and acting on the transverse components of magnetization $M_{x,y}$, and d is the dimension in which displacements are measured ($d = 1$ for diffusion measurements along one axis). The signal intensity is then damped by a factor

$$S(\boldsymbol{q}) = \exp\left[-(2\pi)^2 \boldsymbol{q}^2 D\Delta\right] \tag{17}$$

This factor can be multiplied into an equation such as Equation 15 where D can also be assumed to be dependent on position, $D(x,y,z)$. The vector $\boldsymbol{q}$ is the area of one of the lobes of the bipolar gradient and is thus mathematically equivalent to the definition of $\boldsymbol{k}$ (see Section 5.1 for a more detailed description).

Image contrast arises because volume elements containing fluid with a larger diffusion coefficient will have a lower intensity. Fluid distributions with different viscosities, or fluids in materials with geometrical confinement, can be visualized by diffusion contrast methods. (see Fig. 13). In the latter case, restricted diffusion is observed if the mean-square displacement during Δ is comparable to the restriction size. Typical values of encoding times Δ in these types of experiments are on the order of 0.1 – 100 ms, and displacements are in the range of 0.1 – 10 µm for liquids.

The vectorial dependence of the displacement can be exploited to determine anisotropies of diffusion processes by repeating the experiment with bipolar encoding gradients in differ-

ent directions. A prominent example from medical diagnosis is diffusion tensor imaging in the brain which is called "fiber tracking": the diffusion coefficient component along the nerve bundles is larger than the component perpendicular to it due to the geometrical restriction of the latter.

3.3. Chemical Shift Imaging

Unique to NMR, and therefore the most powerful "contrast" of MRI, is its capability to differentiate the chemical constitution of the material via the chemical shift dispersion of the nuclei to be examined. In conventional NMR spectroscopy, the FID is acquired in a magnetic field of maximum homogeneity by subsequent Fourier transformation, which allows one to distinguish chemical shift and hyperfine coupling effects down to frequency differences of less than 1 Hz, requiring field homogeneities of 10^{-10} or better [1]. This immediately prohibits the combination of frequency encoding with direct NMR spectroscopy; instead, phase encoding methods must be applied which are characterized by signal acquisition in a homogeneous field.

Figure 14. Chemical shift imaging (CSI) sequence with slice selection along z, and phase encoding along x and y spatial dimensions. The NMR signal is acquired in the absence of gradients. The sequence prior to signal acquisition can be regarded as a filter delivering chemical shift spectra for each of the image pixels within the slice.

The most prominent pulse sequence to obtain an image in which each pixel contains a full chemical shift spectrum is called chemical shift imaging (CSI). Figure 14 illustrates a CSI imaging sequence in which a slice dimension and two orthogonal dimensions of spatial encoding are defined before acquiring the signal in the absence of a magnetic field gradient. Each NMR spectrum obtained corresponds to a single point in 2D k space and delivers full chemical shift information for each pixel in the image after Fourier transformation, but it still involves averaging over the thickness of the excited slice. However, one can even replace the slice gradient by one further variable phase-encoding gradient along the remaining axis. One then performs a truly four-dimensional experiment, since it relates the signal in the (k_x,k_y,k_z,t) space to the information in the (x,y,z,ω) space by a four-dimensional Fourier transformation. CSI is therefore the most informative, but also the most time-consuming approach.

Figure 15. The effect of an rf pulse with finite bandwidth (indicated by the shaded area) on the NMR spectrum. Relative to the undisturbed spectrum (top), the spectrum following the frequency-selective pulse consists of a line within the bandwidth, and possibly of remainders of the other lines at much reduced intensity.

Instead of acquiring the entire chemical shift information as an extra dimension, one can reduce one dimension by utilizing frequency-selective rf pulses which only excite a nar-

Figure 16. Imaging of ^{129}Xe using a) regular imaging and b) chemical shift selective imaging sequence along the cross section of three NMR tubes containing toluene, water, and benzene. All tubes contained dissolved hyperpolarized ^{129}Xe in the solvent. Selective excitation selected only the desired substance as is demonstrated for ^{129}Xe dissolved in water.

row bandwidth of interest. Here, the frequency-selective pulse acts as a filter prior to the imaging sequence and imposes a contrast on the image reflecting the chemical composition of the sample. Figure 15 symbolically describes the effect of such a pulse under realistic conditions: out of a spectrum of several lines, the selective pulse excites only spins with frequencies within its bandwidth, but often the remaining lines are not perfectly suppressed, a problem which requires more elaborate sequences in those frequent cases where a diluted component has to be highlighted with respect to a strong solvent background.

Figure 16 illustrates the effect of chemical shift selective imaging on three NMR sample tubes containing toluene, water, and benzene placed inside an NMR imaging probe. Hyperpolarized ^{129}Xe (see Section 6.3) was inserted into all three tubes and subsequently the ^{129}Xe NMR signal was obtained. ^{129}Xe has a large chemical shift range so that different solvents such as toluene versus benzene lead to a 10 ppm shift which renders chemical shift selective imaging very easy. In a), a regular spin warp imaging sequence was applied and in b), only the ^{129}Xe dissolved in water was selectively irradiated in order to obtain an image only from the water-containing part of the sample. Note that in principle, the same procedure can be carried out by utilizing the ^{1}H signals of the solvents themselves, but the much smaller chemical shift range of the hydrogen nuclei makes this a less straightforward experiment.

Another approach to obtain spatially selective chemical shift information is, instead of obtaining the entire image, to select only the voxel of interest of the sample and to record a spectrum. This method called volume-selective spectroscopy (VOSY) [29] is a 1D NMR method and is accordingly fast compared to a 3D sequence such as CSI. In Figure 17, a VOSY sequence based on a stimulated echo sequence is displayed, where three slice-selective pulses excite coherences only inside the voxel of inter-

Figure 17. Volume-selective spectroscopy (VOSY) sequence based on a stimulated echo sequence using three selective pulses of arbitrary flip angle (α_1, α_2, α_3). These soft pulses are used for volume selection along x, y, and z. The echoes V_1 and V_2 are generated as an effect of all three rf pulses and can be exploited directly for localized spectroscopy of the selected volume, while the echoes L_1, L_2, and L_3 are generated by different combinations of two rf pulses and represent the averaged spectra within three orthogonal lines crossing at the center voxel.

Figure 18. Volume-selective spectroscopy (VOSY) within a fixed bed of 20 mm diameter. A) Two-dimensional spin density image within a 0.5 mm thick slice near the center of the fixed bed. Selected volumes of 1.5 × 1.5 mm are indicated. B) Section of ^{1}H spectra covering the chemical shift range of the interparticle OH line; spectra were taken in the selected volumes shown in a); the acquisition time for each spectrum was 3 min. (Reproduced from [30] with permission).

est. The offset frequencies of the slice-selective pulses define the location of the voxel. Along the receiver axis all FIDs and echoes created by this stimulated echo sequence are displayed; they contain signals from different regions of the sample. Figure 18 demonstrates how such a sequence can be employed for monitoring an esterification reaction: the ^{1}H chemical shift of an OH line is a function of the pixel coordinates for different positions within a resin bed of 20 mm diameter. This chemical shift is a function of the relative amounts of acetic acid, methanol, and water because hydroxyl protons undergo fast exchange between these three molecules, which results in a weighted average of the corresponding spectral frequencies. The local concentration of acetic acid is thus directly obtained from the chemical shift, and the extent of conversion can be followed with spatial resolution by acquiring a series of VOSY spectra.

3.4. Spin Density and Parameter Images

Discussion about contrast in NMR imaging can be continued extensively. Merely the most basic contrast parameters for NMR imaging have been mentioned. There are endless varieties of "filter" sequences that can be set prior to an imaging sequence to specifically weight or select the NMR signal according to the nature of the physicochemical "filter". For instance, contrast representing dipolar coupling of various strength, order, and alignment, viscosity, and temperature can be created, to name just a few examples.

While filters can be applied at will, and serve for generating images weighted with a particular property, the two contrast parameters T_1 and T_2 cannot be "switched off", since the execution time and repetition time in any imaging experiment are finite. Only with knowledge of the relaxation properties is it possible to reconstruct the "true" spin density distribution. From the structure of Equation 15 it is clear that this can only be achieved by a comparison of signal intensities with different values of TE and TR, which requires at least three combinations of these waiting times. The signal intensity can then be extrapolated to TE = 0 and TR = ∞. This is based on the assumption that relaxation can be described by an exponential relation; otherwise, reconstruction requires some assumptions and, to minimize errors, short TE and long TR within the experimentally accessible range are preferred.

From comparing two or more images with a different weighting, it is just one more step to generating a proper parameter image. The difference is as follows: a weighted image still contains the spin density in the signal amplitude and represents a classical contrast image, whereas a parameter image only contains the values of the pure parameter (e.g., diffusion coefficient, T_1, T_2) in each pixel. For example, one can obtain two images with different TE while keeping all

Figure 19. Partially regenerated, coked Al_2O_3 catalyst samples with the same residual coke content of 7.65 %. Left: regenerated at 550°C; right: regenerated at 400°C. A) Optical photographs of cut samples; B) NMR images with the relaxation time T1 as contrast parameter; C) Radial coke profiles determined from B), compared to electron microprobe measurements and simulated distributions.

other variables unchanged. Dividing the images pointwise

$$\varrho\,(x,y,z)\ \exp\left[-\mathrm{TE1}/T_2\,(x,y,z)\right] \\ /\varrho\,(x,y,z)\ \exp\left[-\mathrm{TE2}/T_2\,(x,y,z)\right] \\ = \exp\left[(\mathrm{TE2}-\mathrm{TE1})\ T_2\,(x,y,z)\right] \tag{18}$$

renders an image that contains the relaxation times averaged within each volume element. Figure 19 shows an example from chemical engineering: alumina pellets that have been used in hydrocarbon conversion accumulate coke residues on their internal and external surfaces which partially block the pore structure. Regeneration, i.e., removal of the coke, depends on the process temperature and is more homogeneous at lower temperatures. The coke-free zones at an intermediate stage of regeneration are easily visible, but the correlation of the relaxation time T_1 with coke content allows the reconstruction of a coke concentration profile across the pellet.

4. Fast Imaging Techniques

To speed up imaging, waiting times for retrieving full equilibration of magnetization before each subsequent encoding step are prohibitive. It therefore appears that relaxation weighting becomes unavoidable if fast imaging experiments are to be performed. However, there are fundamentally different approaches that, with modern

hardware, eventually reduce the acquisition time of three-dimensional images down to about one second. One can distinguish four strategies to achieve this goal: successive excitation of different partial volumes of the sample, successive excitation of fractions of the total magnetization by short rf pulses, generation and repeated encoding of a train of spin echoes, and the same approach for gradient echoes.

4.1. Multislicing Methods

One rather straightforward way to minimize image acquisition time is to expand the method of slice selection introduced in Section 2.3. Not only the thickness but also the position of the excited slice can be manipulated by varying the carrier frequency of the soft rf pulse. The same kind of 2D imaging experiment can thus be performed as was shown in Figure 7, but with each encoding step performed within a slice at a different position in the object. A series of slices can be defined in such a way that the total volume is covered, and 2D images within each slice can be combined to a 3D image of the object. Therefore, there is no need for a waiting time after the end of data acquisition, and the next encoding step can be applied immediately afterwards but for a different slice. The first slice can again be addressed after a total time of approximately 5 T_1 during which each slice has been excited once. The principle of multislicing is shown in Figure 20.

4.2. Nonequilibrium Methods

Another means for overcoming the dilemma of long experimental times is to employ small flip angles for the pure phase-encoding sequence. In the picture presented in Figure 1, transverse magnetization can be generated by an rf pulse of arbitrary length; out of the initial value M_0, a fraction $\sin\theta$ (where θ is the flip angle) is rotated into the transverse plane which is available for image encoding, and the remaining amount $(1-\sin\theta)$ is preserved. Because there is no longer the need to wait a multiple of the relaxation time T_1 for recovery of magnetization, much shorter repetition times can be used between the phase-encoding cycles. This method is termed fast low-angle shot imaging (FLASH) [31]. The fast repetitive excitation of the residual z magnetization causes signal depletion, but this is compensated to a certain degree by partial magnetization recovery due to spin – lattice relaxation. A typical flip angle (θ in Fig. 21) would be 5°. In reducing the flip angle, the total image acquisition time of FLASH is shortened at the expense of the image signal magnitude. Thus, it is possible to trade off imaging speed and signal-to-noise ratio in a controllable manner. Once an equilibrium between excitation and relaxation has been reached, the optimum flip angle is expressed by the so-called Ernst angle relation:

$$\cos\theta = \exp\left(-\mathrm{TR}/T_1\right) \tag{19}$$

Figure 20. Schematic of multislicing. By shifting the carrier frequency of the soft pulse, slices at different positions of the object are excited. The first soft pulse selects slice 1, and a line in 2D k space within this slice is acquired by setting a particular value of the phase gradient. This encoding is then repeated for slice 2, and so forth. At the last slice, the magnetization in slice 1 has fully relaxed and the next phase-encoding step can be carried out at this position. After the end of the experiment, data must be rearranged so that individual reconstruction of the 2D images in each slice is possible. Note that small gaps between slices may be used to avoid cross-talk; alternatively, one can avoid scanning of successive slices by choosing, for instance, the order 1 – 6 – 2 – 7 – 3 – 8 – 4 – 9 – 5 – 10.

A fast imaging technique particularly tailored for examining solid samples with extremely short T_2^* relaxation time is to employ pure phase encoding, acquire a single point instead of a full FID, and leave the phase encoding gradients

turned on during the entire sequence in order to save the time normally invested into switching and stabilizing of the gradient. Under such conditions, neither the generation of an echo nor the execution of a slice-selective pulse is feasible because of the fast coherence loss of the magnetization. The basic scheme (single-point imaging, or SPI) is sketched in Figure 22A, where gradients along all three coordinates are varied independently of each other.

The modification of the weight function to access the $\boldsymbol{k}$ vector can also be realized via a step-like or continuous change of the gradient function. The acquisition of only one point per phase encoding cycle, i.e., rf pulse and gradient step (single-point ramped imaging with T_1 enhancement, or SPRITE, [32]) with minimized dead time and waiting time between rf pulse and acquisition makes this sequence fast and robust. A two-dimensional realization of this method is shown in Figure 22B, where both gradients are modulated in a sinusoidal fashion in order to avoid large sudden gradient changes and to reduce total energy dissipation; by this method, k space is scanned in a spiral originating at the origin. An experimental result of 2D and 3D SPRITE experiments with optimized k space coverage is shown in Figure 23.

Figure 21. Gradient-echo pulse sequences based on low flip angles, known by the acronym FLASH (fast low-angle shot) imaging [31]. The initial rf pulse defined the excited slice; the coherence of the signal is then re-established by a gradient echo in "read" direction. For each repetition, a different value of the phase-encoding gradient is set, so that a fast 2D image within the defined slice can be acquired.

Figure 22. A) Basic principle of the single-point imaging (SPI) scheme. Gradients in three orthogonal directions are varied independently of each other. One single point is acquired for each combination of gradient values, with the encoding time tp between rf pulse and acquisition event ideally kept as short as possible, taking the dead time of the receiver into account. Gradients are switched on a finite period before the rf pulse to avoid detrimental effects of gradient rise time and eddy currents. B) 2D Spiral-SPRITE method. Gradients are kept constant only during rf pulse application and data acquisition. Because of the sinusoidal modulation of the gradient intensities, the change of the gradient values between successive acquisitions is minimized, allowing for shorter prepulse delays. (Reproduced from [33] with permission).

Figure 23. SPRITE experiments on a cross-linked *cis*-polybutadiene disk manufactured for demonstrating spatial resolution. Left: sample geometry; outer diameter: 43 mm, outer ring (invisible in experiment) thickness: 2.5 mm; diameter of the holes: 1.0, 1.25, 1.75, and 2 mm (NW to SW). The material has a short T_2 relaxation time of 560 ms that excludes conventional imaging based on spin echoes. Center: 2D SPRITE image with 64 × 64 pixels, experiment time 16 s. Right: 3D SPRITE image with 64 × 64 × 64 voxels, experiment time 112 s. The images were acquired with an optimized *k* space trajectory discussed in [34] (reproduced with permission from the authors).

4.3. Multiple Spin-Echo Sequences

The fundamental idea behind the basic spin-echo sequence shown in Figure 1 (and combined with position-encoding magnetic field gradients in Figs. 3, 7, and 8) can be extended to produce a series of echoes. Under the influence of local field inhomogeneities or chemical shift differences, the spin isochromats maintain their individual differences in Larmor frequency and are beginning to dephase again from the moment of the echo maximum. As was pointed out above, the second half of the echo is equivalent to an FID, so it can be taken as a new starting point of a pulse sequence. Another 180° pulse has the effect of refocusing the dephasing transverse magnetization, and generates a second echo. A series of 180° pulses can thus be employed to produce a train of hundreds or thousands of echoes, each of them reduced in amplitude by spin – spin relaxation with a time constant T_2 to a fraction $\exp(-t/T_2)$ of the FID amplitude, where t is the total elapsed time since the first 90° rf pulse. With appropriate phase cycling of the pulses, this method is called the Carr–Purcell–Meiboom–Gill (CPMG) sequence and constitutes the standard sequence for measuring T_2.

Rather than just determining the amplitude of each echo, one strategy for performing fast imaging is to encode position information into each echo in a different way, e.g., by applying phase gradients of different strength between the rf pulses and reading the signal intensity with a frequency encoding gradient. Depending on the duration of signal acquisition and the value of T_2, all necessary phase encoding steps, or at least

Figure 24. RARE sequence for fast imaging. The formation of the first spin echo is similar to a conventional imaging sequence such as that shown in Figure 8, but in this case all rf pulses are considered slice-selective. All further spin echoes are encoded by phase gradients of different strength. The CPMG form of spin echo is used to avoid the accumulation of flip-angle errors over the echo train. However, before the following echo can be acquired, the phase-encoding has to be "rewound" to undo the dephasing of the spins. Therefore, a phase encoding step of equal strength but opposite sign is applied after the completion of each data acquisition. If the entire *k* space data set is to be acquired with multiple RARE echo trains, the whole sequence is repeated with different phase-encoding steps until the entire *k* space is covered.

several of them, can be performed within a single echo train. One prominent sequence based on multiple spin-echoes that works according to this principle is called rapid acquisition with relaxation enhancement (RARE) [35]. The so-called turbo spin-echo (TSE) sequence is a commercial version of RARE. RARE is based on a CPMG echo train and is displayed in Figure 24. Acquisition of the first echo signal is conventional; it includes a phase-encoding and a read gradient. However, before the second echo can be acquired, the phase encoding must be "rewound" to undo the dephasing of the spins. Rewinding is realized by a phase-encoding step of equal strength but opposite sign applied after completion of data acquisition. At this instance, the total phase shift of the isochromats due to position encoding is zero, so that each 180° pulse acts on the system with equal properties. The whole sequence is repeated after a recovery time with different phase encoding steps. Within one echo train, a portion of k space is covered. So, if l echoes are acquired per scan, and n scans are carried out with varying phase-encoding gradients, a total of $l \times n$ number of lines in k space will be collected. In other words, each echo is responsible for a different portion of k space. One drawback is that different lines of k space will have different T_2 weighting because they are acquired at different echo times. Depending on the exact design of the sequence, one can assign any of the echoes to coincide with the center or outer part of k space, which then affects the contrast of the image.

The use of rewinding gradient pulses has made RARE rather robust since, particularly in structured media, magnetic fields inside the sample are intrinsically inhomogeneous so that local shifts in resonance frequencies and thus phase errors are unavoidable. If this problem is less pronounced, a "blipped" version of a multiple spin-echo sequence can be employed, where the increase of the value of k in phase direction is achieved in a cumulative manner by applying the same, small PFG (so-called "blip") before each echo acquisition. Avoiding the rewinding gradient saves time in the execution of the pulse sequence. In a similar fashion, a number of other variations based on the principle of spin echoes have been suggested.

4.4. Multiple Gradient Echo Sequences

In the quest to reduce the experiment time for acquiring a series of echoes with different positional encoding, the necessary waiting times for generating spin echoes are a disadvantage. Likewise, a compromise must be made between image resolution and acquisition time – a high resolution requires the readout of many points during the acquisition period, so that acquisition time can eventually only be saved at the cost of limited resolution. The theoretically fastest NMR imaging sequence is defined in such a way that a maximum of the experimental time is used for gathering information, i.e. the final goal would be to achieve quasicontinuous data sampling. The use of gradient echoes instead of spin echoes almost matches this theoretical limit.

Figure 25 shows the principle of an imaging sequence based on multiple gradient echoes, called echo planar imaging (EPI) [36] because it was initially designed for the rapid acquisition of a 2D image of a slice that is defined by the

Figure 25. Echo planar imaging (EPI) pulse sequence. Gradient-echo-based multiple echoes are used for fast single-shot 2D imaging. Slice selection along G_s and frequency encoding along G_r is utilized. Phase encoding is realized by using short "blipped" gradient pulses along G_p.

initial soft 90° pulse. No further rf pulses are used throughout this sequence.

According to the above definition, EPI is the fastest pulse sequence available, offering acquisition times of 100 ms or less for 2D images. Its main disadvantage is the fact that the echoes are generated by the rephasing effect of the applied gradients themselves, which alternate in sign; however, the effects of background gradients and chemical shift differences are not refocused. EPI is best used with objects of rather homogeneous magnetic field distributions, and with spectra in which the chemical shift difference is negligible. The train of echoes and the image intensity itself are T_2^*-weighted. An EPI image is thus feasible only when T_2^* of the FID exceeds the total acquisition time of the echo train; this can serve as a first test of the applicability of EPI. In the version depicted in Figure 25, the variation of the phase direction of k space is achieved by small "blip" gradient pulses (see discussion in Section 4.3). The blips can be replaced by a constant, weak gradient that leads to a continuous accumulation of the signal phase, which is interrogated at the position of each echo; the definitions of "phase encoding" and "frequency encoding" then lose their meaning in the strict sense, since the complete signal evolution takes place in the presence of magnetic field gradients.

Again, there are a number of further modifications to EPI sequences. Common to all is the need for high-quality gradient coils and amplifiers that allow the quick change of large currents in a defined and reproducible way.

5. Measurements of Transport Processes

In many modern applications of medical and nonmedical MRI, the investigation of motion has become the focus of attention. With comparatively little modification to the basic pulse sequences, motion can be detected by standard MRI hardware, while many other, classical techniques are only capable of generating still images. There are again two fundamentally different approaches to NMR imaging of motion: first, a quick succession of images acquired with the methods discussed in Chapter 4 is suitable to visualize transient phenomena on timescales of tens of milliseconds; these so-called cine methods have successfully been used for generating movies of, for instance, beating hearts in animals. This application can be regarded as a straightforward extension of pure imaging.

It is, however, also possible to encode parameters such as velocity or diffusion coefficients into an image, without the need to acquire two different images sequentially. The encoding takes place by pulsed field gradients of suitable properties. In the following three sections, the fundamental relationships of these dedicated methods are summarized. A different approach, exploiting various aspects of time-of-flight effects, is briefly discussed in Section 5.4.

5.1. q Space

The $\boldsymbol{q}$ vector was already introduced in Equation 17 in the context of diffusion measurements. More generally, it is used in experiments in which motion is to be quantified. In Figure 26, the simplest pulse sequence for determining motion by NMR is shown.

Figure 26. Basic pulse sequence for detecting motion. At the time of the spin echo, phase differences due to time-invariant field inhomogeneities and chemical shift differences are refocussed (see Fig. 1). The application of two pulsed gradients with the same area but opposite (effective) sign has no effect on static matter, but imposed a phase shift onto spins which have moved during Δ.

The transverse component of the magnetization $M_{x,y}$ accumulates all phase shifts that are imposed by position-dependent magnetic fields between the initial 90° rf pulse and data acquisition at the time of the echo. In this sequence, the magnetization experiences two pulsed gradients with equal area but opposite sign (note that all 180° pulses have the effect of alternating the sign of any PFG that was applied before the pulse). It can be regarded as a double encoding of posi-

tion, occurring at different times separated by a delay Δ.

The total phase can be written as

$$\begin{aligned}\phi(\boldsymbol{r}_1,\boldsymbol{r}_2) &= \gamma\delta(\boldsymbol{g}_1\boldsymbol{r}_1+\boldsymbol{g}_2\boldsymbol{r}_2)\\ &= 2\pi(\boldsymbol{k}_1\boldsymbol{r}_1+\boldsymbol{k}_2\boldsymbol{r}_2)\\ &= 2\pi\boldsymbol{k}_1(\boldsymbol{r}_1-\boldsymbol{r}_2)\\ &= -2\pi\boldsymbol{q}\,\boldsymbol{R}\end{aligned} \tag{20}$$

where $\boldsymbol{r}_1$, $\boldsymbol{r}_2$ are the positions at the time of the first and the second gradient pulse, respectively. Because of the interdependence of the gradients, only one variable wave vector remains, and it determines the phase shift proportional to the displacement $\boldsymbol{R}$. Note that, by applying a matched pair of gradients, the information about position is totally removed and is replaced by a measure of displacement of spins at any (undefined) position within the sample.

In order to symbolize that displacements are encoded rather than positions, the corresponding wave vector is renamed $\boldsymbol{q}$. While it is obvious that $\boldsymbol{q} = \boldsymbol{k}_1 = -\boldsymbol{k}_2$, a change of variable names often facilitates the discussion of more complex encoding schemes when distinguishing whether position or displacement ought to be encoded. In most, but not all, recent works, $\boldsymbol{q}$ is used for the Fourier conjugate variable to $\boldsymbol{R}$.

The signal, expressed as a function of $\boldsymbol{q}$, can now be written as

$$S(\boldsymbol{q}) = \int \bar{P}(\boldsymbol{R},\Delta)\,\exp[i2\pi\boldsymbol{q}\,\boldsymbol{R}]\,\mathrm{d}\boldsymbol{R} \tag{21}$$

Equation 21 is formally equivalent to Equation 10 defining position encoding, but it contains as the kernel the distribution function of displacements $\int \bar{P}(\boldsymbol{R},\Delta)$. This function is also called the *propagator* and it should, if correctly used, include one further variable, the encoding time Δ between the gradient pulses over which the displacement $\boldsymbol{R}$ is determined. It is important to take Δ into consideration, because in many real situations not only the average displacement but also the shape of the propagator will depend on the length of the interval during which it is being measured.

The bar above the symbol of the propagator denotes an ensemble average over the whole sample, or a selected volume of it; the position information is lost. The averaging is contained in the formal description of the propagator, which can be written as

$$\bar{P}(\boldsymbol{R},\Delta) = \int \varrho(\boldsymbol{r}_1)\,P(\boldsymbol{r}_1|\boldsymbol{r}_1+\boldsymbol{R},\Delta)\,\mathrm{d}\boldsymbol{r}_1 \tag{22}$$

In this expression, the propagator is decomposed into the *spin density* at the initial position $\varrho(\boldsymbol{r}_1)$ and the *conditional probability* that a particle moves from $\boldsymbol{r}_1$ to a position $\boldsymbol{r}_1+\boldsymbol{R}$ during the interval $\Delta P(\boldsymbol{r}_1|\boldsymbol{r}_1+\boldsymbol{R},\Delta)$. Note that neither of these functions can be directly retrieved because they are "hidden" in the integral. The propagator experiment is one-dimensional since it involves the simultaneous variation of both gradient pulses; however, by making use of more complex and higher dimensional experiments, conditional probability functions such as that mentioned here can indeed be determined [18, 37].

Just as the spin density distribution $\varrho(\boldsymbol{r})$, and hence the projection of the investigated object, is obtained in phase encoded imaging, $\bar{\boldsymbol{P}}(R,\Delta)$ can be reconstructed by applying the inverse Fourier transformation to $S(\boldsymbol{q})$, where one has to scan $\boldsymbol{q}$ space by varying the strength of the gradient pair. The resulting propagator might not be as intuitive as the function $\varrho(\boldsymbol{r})$, but it is a valuable tool to check distributions of displacements or velocities by comparing them with particular models. Some classical examples are given here.

Perhaps the simplest flow problem is that of laminar flow along z through a cylindrical pipe of radius r_0. For this so-called Poiseuille flow, the axial velocity v_z depends on the radial coordinate r as $v_z(r) = v_{\max}\lfloor 1-\left(\frac{r}{r_0}\right)^2\rfloor$, which is a parabolic distribution with the maximum flow velocity in the center of the pipe and zero velocity at the wall. The distribution function of velocities is obtained from equating $\int P(r)\,\mathrm{d}r = \int P(v_z)\,\mathrm{d}v_z$ and the result is that $P(v_z)$ is a constant between 0 and $v_{\max}$. The propagator has the same shape, as it measures the distribution of downstream displacements, $Z = v_z\Delta$. Often, the name propagator is used synonymously for the distribution of velocities; this is justified in this and similar cases, but not in general.

Figure 27 compares a sketch of the parabolic velocity profile with an example of an experimentally obtained propagator $P(Z)$ for flow in a pipe. It turns out that for this simple case, the shape of the distribution function is very sensitive to imperfections in the flow, which makes determination of the propagator a suitable method to assess the quality of laminar flow

conditions. For instance, at a closer look, the rectangular shape of the propagator is broadened by self-diffusion that takes place both parallel and perpendicular to the flow direction, and thus depends on the measurement time: for very short Δ, self-diffusion contributes a considerable broadening while for long Δ, radial Taylor dispersion leads to a change of flow velocities, and also smoothes the edges of the propagator. It has been found that subtle changes in propagator shape can be distinguished far better than direct determinations of velocity differences at a given point.

Figure 27. Left: schematic plot of the distribution of flow velocities v_z for laminar flow of a Newtonian fluid in a circular pipe; the maximum value of the velocity, which occurs in the center of the pipe, is drawn for comparison. Right: experimentally obtained propagator of water flowing under laminar conditions in a circular pipe; the probability density of displacements is constant between 0 and $Z_{\max} = v_{z,\max}\Delta$ where Δ is the encoding time of the experiment.

In Figure 28, the propagator of free self-diffusion is shown. Actually, self-diffusion was the first case for which the propagator terminology was discussed in the NMR context [38]. The propagator of free diffusion is of Gaussian shape; the mean-squared displacement of spins or molecules follows the same Gaussian evolution as the concentration of a pointlike source. It is of the form

$$\bar{P}\left(\boldsymbol{R},\Delta\right) = \left(4\pi D\Delta\right)^{-3/2} \exp\left[-\boldsymbol{R}^2/6D\Delta\right] \tag{23}$$

and is identical in all three directions. The result of an NMR experiment with an encoding wave vector $\boldsymbol{q}$ is as follows:

$$S\left(\boldsymbol{q}\right) = \exp\left[-(2\pi)^2\boldsymbol{q}^2\,\boldsymbol{R}^2/2\right] \tag{24}$$

This is again a Gaussian function. By using Einstein's equation (Eq. 16) one obtains the signal decay due to diffusion that was employed above (Eq. 17).

Figure 28. Top: propagator for unrestricted self-diffusion. The propagator $\bar{P}\left(\boldsymbol{R},\Delta\right)$ is shown for increasing encoding times Δ and becomes broader with increasing Δ, while its intensity at zero displacement is reduced due to requirement that the area remains normalized to unity. Bottom: signal function S($\boldsymbol{q}$) as would be obtained in an experiment, plotted semi-logarithmically against $\boldsymbol{q}^2$. In this representation, the slope of the decaying function is equal to $(4\pi)^2\Delta D$, so that the diffusion coefficient D can be obtained directly from comparing at least two measurements taken at different values of $\boldsymbol{q}$.

The Gaussian shape of a propagator leads to considerable advantage as far as NMR experiments are concerned: it is not necessary to resolve the complete shape of the propagator, which is fully described by three parameters: amplitude, center position, and width. While the amplitude is usually irrelevant and the average

displacement of free diffusion is zero (which has the consequence that the signal function $S(\boldsymbol{q})$ contains no complex phase factor), only the width of the propagator is of interest. One can obtain this quantity by performing a simplified experiment. If one plots $S(\boldsymbol{q})$ as ln S versus $\boldsymbol{q}^2$, a straight line is obtained (right part of Fig. 28). The slope of this line is proportional to the self-diffusion coefficient D and can — at least in principle — be obtained by measuring at just two different $\boldsymbol{q}$ values.

Restricted diffusion, correlated motion of spins, or any deviation from a "free" behavior of the molecules will result in a non-Gaussian propagator shape. A wide range of studies have dealt with such problems during the last two decades, and NMR has turned out to be the method of choice for quantifying restricted-diffusion phenomena such as liquids in porous materials and dynamics of entangled polymer molecules; for an overview of methods, see [39, 40]. For pure displacement measurements like this, the term "q space imaging" has been coined, which is somewhat misleading, since it describes the visualization of statistical distributions of displacements, instead of real images.

5.2. Motion Encoding and Moments

From the discussion of bipolar gradients in Section 3.2, it becomes clear that NMR pulse sequences can be designed which contain information about position, velocity, and potentially other parameters that are related to motion [41, 42]. The individual tools that PFGs provide for the encoding are best explained by extending the relationship for the accumulated phase shift in the presence of a magnetic field gradient (Eq. 9) towards a general expression that allows for variation of gradients and positions with time:

$$\phi(\boldsymbol{r},t) = \int_0^t \omega(t') \cdot \boldsymbol{r}(t')\,\mathrm{d}t' = \int_0^t \gamma \boldsymbol{g}(t') \cdot \boldsymbol{r}(t')\,\mathrm{d}t' \tag{25}$$

If the position of a spin is expanded into a Taylor series:

$$\boldsymbol{r}(t) = \boldsymbol{r}_0 + \boldsymbol{v}_0 t + \frac{1}{2}\boldsymbol{a}_0 t^2 + \ldots \tag{26}$$

one obtains [18]:

$$\begin{aligned}\phi(\boldsymbol{r},t) &= \gamma \int_0^t \boldsymbol{g}(t') \cdot \left[\boldsymbol{r}_0 + \boldsymbol{v}_0 t' + \tfrac{1}{2}\boldsymbol{a}_0 t'^2 + \ldots\right] dt' \\ &= \gamma \left[\boldsymbol{r}_0 \int_0^t \boldsymbol{g}(t')\,\mathrm{d}t' + \boldsymbol{v}_0 \int_0^t \boldsymbol{g}(t')\,t'\mathrm{d}t' \cdot \right. \\ &\quad \left. \tfrac{1}{2}\boldsymbol{a}_0 \int_0^t \boldsymbol{g}(t')\,t'^2\,\mathrm{d}t' + \ldots\right] \\ &= \gamma\left[\boldsymbol{r}_0\boldsymbol{m}_0 + \boldsymbol{v}_0\boldsymbol{m}_1 + \tfrac{1}{2}\boldsymbol{a}_0\boldsymbol{m}_2 + \ldots\right]\end{aligned} \tag{27}$$

Figure 29. Typical pulsed gradient shapes commonly used for imaging or measurements of motion. a) A single gradient pulse, which is used for phase encoding of position, also has all other moments nonvanishing, so that the signal phase is affected by position, velocity, and acceleration. b) A bipolar gradient is the basic building block of most measurements of diffusion or flow; due to its vanishing zeroth moment, its application does not contain any position information. c) A phase-encoding gradient that is insensitive to motion needs a more complex shape; at least of two lobes are required. d) Two bipolar gradients arranged back-to-back generate an encoding that is affected neither by position nor by velocity, but higher order terms such as acceleration can be measured. The variant shown in e) is equivalent to d) but with the time intervals between pulses kept to a minimum. Note that in all cases, the effective gradient is shown; each 180° rf pulse applied anywhere within the sequence has the effect of reverting the sign of all gradient pulses that precede it so that the effective gradient becomes the negative equivalent to the physically applied gradient.

Terms of higher order than acceleration are usually not considered in NMR experiments. One can thus identify three integrals which are the respective Fourier conjugates to position $\boldsymbol{r}_0$, velocity $\boldsymbol{v}_0$, and acceleration $\boldsymbol{a}_0$:

The zeroth moment $\boldsymbol{m}_0$ was already mentioned briefly in Section 2.4. It is nothing else than the total area of the gradient (see Fig. 29a). If the area vanishes, the signal is independent of spin position. This is the case, for instance, for a bipolar gradient with positive and negative lobes of equal area (see Fig. 29b).

The first moment $\boldsymbol{m}_1$ encodes velocity. One can easily show that the bipolar gradient in Fig. 29b has a first moment of $\boldsymbol{m}_1 = \boldsymbol{g}\delta\Delta$, while $\boldsymbol{m}_0 = 0$. Symmetric gradient pairs are therefore the simplest way to measure velocities while introducing no effect of position on the signal, i.e., the velocity encoded by such a gradient pair alone represents all spins in the whole sample. If phase encoding is to be achieved without an additional influence by velocity, the conditions $\boldsymbol{m}_0 \neq 0, \boldsymbol{m}_1 = 0$ must be met simultaneously (see

Figure 30. A) Pulse sequence for encoding of displacements in two dimensions. The sequence is based on the one-dimensional case (Fig. 26) but a stimulated echo is used instead of a spin echo; such a sequence adds further flexibility to the investigated timescale, since the encoding time Δ can be varied over a wider range compared to the spin-echo sequence, since the magnetization decays only with a time constant T_1 between the second and the third rf pulses. Both gradient pairs (in this case, G_x and G_z) are varied independently of each other. B) 2D propagators for water flowing through a random bed of monodisperse glass beads (600 mm diameter) at an average interstitial velocity of 2.5 mm/s for encoding times Δ indicated above the diagrams. The contour lines indicate the probability of displacements along the flow axis (Z) and perpendicular to it (X). (Reproduced from [46] with permission).

Fig. 29c, and the more detailed discussion of Fig. 33 in Section 5.3).

The second moment, $\boldsymbol{m}_2$, encodes acceleration. If only acceleration is to be measured, the conditions $\boldsymbol{m}_0 = 0, \boldsymbol{m}_1 = 0$ must be fulfilled. Figure 29d and e show two commonly used realizations. See [43 – 45] for applications in which acceleration is measured by NMR.

The discussion of "q space imaging" and similar concepts to measure displacements has been limited to one-dimensional experiments so far. However, just like in k space, experiments of higher dimension can be performed, although their interpretation requires more care.

The direct counterpart of 2D phase encoding of position is the 2D propagator, where gradient pairs are applied simultaneously but in orthogonal directions and varied independently of each other (see Fig. 30). What is obtained is a two-dimensional distribution function, $\bar{\bar{P}}\,(X,Z,\Delta)$, that can, for instance, be used to investigate how displacements along a flow axis Z are related to those perpendicular to the flow axis X. An example for flow of water through a random structure is shown in Figure 30B.

Of even more fundamental interest is probably the comparison of displacements in the same direction but at different times, an experiment called velocity exchange spectroscopy (VEXSY) [47]:

In a 2D VEXSY experiment, two independent pairs of bipolar gradient pulses (with separation Δ between the bipolar gradients) are used to encode displacements. These displacements (or velocities) are correlated at two different times separated by t_{m}, called the mixing time. This is in the form of a classical NMR spectroscopy exchange experiment, which is used to find correlations between features in the frequency spectrum by identification of cross-signals in a two-dimensional density representation $S(f_1, f_2)$ [1, 8]. Following the same principle that these off-diagonal cross-signals represent spins that are correlated and have changed or transferred their properties because of various coupling mechanisms during a mixing period or pulse, the off-diagonal cross-signal in a 2D VEXSY map represents spins that have changed their initial velocity after a mixing time of τ_{m}. The resulting function of a 2D VEXSY experiment is the joint probability density of finding displacements $\boldsymbol{R}_1$ during the first and $\boldsymbol{R}_2$ during the second interval, separated by the mixing time:

$$\bar{\bar{P}}_2\,(\boldsymbol{R}_1,\Delta;\boldsymbol{R}_2,\Delta;\tau_{\mathrm{m}}) = \bar{P}_1\,(\boldsymbol{R}_1,\Delta)\,\mathrm{P_V}\,(\boldsymbol{R}_1,\Delta|\boldsymbol{R}_2,\Delta;\tau_{\mathrm{m}}) \tag{28}$$

where the conditional probability $\mathrm{P_V}\,(\boldsymbol{R}_1,\Delta|\boldsymbol{R}_2,\Delta;\tau_{\mathrm{m}})$, describing the probability of displacement $\boldsymbol{R}_2$ given that it was in the first interval, can be interpreted more easily and is obtained by dividing the 2D function by the simple propagator $\bar{P}_1\,(\boldsymbol{R}_1,\Delta)$ [37].

A 2D VEXSY experiment can be based on a spin echo where transverse magnetization carries the information of the moving spins during τ_{m}, or on a stimulated echo where the longer lived longitudinal magnetization carries the information.

Figure 31 depicts one possible pulse sequence for a VEXSY experiment. Here, the first pulsed gradient pair (wave vector $\boldsymbol{q}_1 = \boldsymbol{k}_1 = -\boldsymbol{k}_2$) is placed between the initial 90° rf pulse and the first spin echo (not shown). The second

Figure 31. Spin-echo-based pulse sequence to encode velocity change. The gradients are stepped pairwise independently (2D VEXSY) or simultaneously (1D VEXSY). For a VEXSY experiment, k_1 to k_4 usually are applied along the same spatial direction. δ is the duration of each gradient pulse, Δ the separation between each pair of bipolar gradient pulses and tm the mixing time between the bipolar gradient pairs. The opposite polarity of the bipolar gradient pair is realized by an 180° inversion pulse.

Figure 32. Example of a VEXSY experiment. In a setup similar to that shown in Figure 30B, water and silicone oil were simultaneously present in a random bed of monodisperse glass beads (400 mm diameter), and either of the two liquids was pumped with no net flow being applied to the other liquid. The average interstitial velocity was 9.5 mm/s (oil flow) and 11.0 mm/s (water flow). Data are shown for mixing times tm in relation to the characteristic correlation time of the system tc, indicating the time to travel one bead diameter. The function plotted is the conditional probability described in the text. The change from high correlation (alignment along the main diagonal) towards complete loss of correlation (horizontal contour lines) is evident with increasing tm. (reproduced from [54] with permission).

180° pulse gives rise to a further echo that is the starting point of the second displacement-encoding module (wave vector $\boldsymbol{q}_2 = \boldsymbol{k}_3 = -\boldsymbol{k}_4$). Only the final echo is acquired and contains the signal of spins that have experienced all four gradient pulses. The $\boldsymbol{q}$ vectors are usually applied in the same spatial direction so that the set of spins traveling at constant velocity will have identical R_1 and R_2 displacements, thus contributing to signal on the diagonal in the (R_1, R_2) space. By contrast, a migration of spins from one region of the displacement spectrum to another over the time τ_m will lead to off-diagonal contributions. The off-diagonal signal represents all spins that have changed their initial velocity, thus revealing complex motion including acceleration. Application of VEXSY, mainly to fluid-flow and particle-motion problems, has become increasingly important in recent years, and the interpretation of such correlations has been discussed by means of coordinate transformations [18, 43, 48] and 1D versions of the experiment [49 – 53]. An example of studies of two-phase flows in which the spectroscopic information of the echo is exploited is shown in Figure 32.

5.3. Velocity Maps

The methods that have been presented in Sections 5.1 and 5.2 generate pure statistical measures of motion parameters. However, it is frequently desirable to obtain a pictorial, and indeed also quantitative, representation of a flow field.

In order to determine the actual motion of a fluid with spatial resolution, and particularly for displacements smaller than the image resolution, the spins must be encoded with respect to position and velocity within a single pulse sequence; this is what can be called velocity imaging in

the "proper" sense. Before this can be achieved, it is vital to understand, and to avoid, the side-effects that flow has on an NMR image, i.e., the possibility of blurring or losing signal from certain volumes because the spins move out of the detection coil before they can contribute to the signal.

Figure 33. Typical motion-compensated, velocity-encoding imaging sequence. The basic scheme from Figure 8 is amended by additional compensating gradient pulses for read, phase, and slice directions. The velocity encoding pair of gradient pulses of duration δ and separation Δ is drawn on a separate line; in reality, it is applied along any of the three directions given for read, phase, and slice. The diagonal lines indicate that the magnitude of this gradient pulse pair is varied in a number of steps; the experiment, however, can also be executed with a single magnitude value by comparison to an equivalent sequence without the velocity-encoding gradients.

In fact, *blurring* — as would be observed in an optical photograph of a moving object — is an inadequate description of the NMR image artefacts arising due to motion, which can be much more complicated that just reducing the spatial resolution of an image. A plethora of ghosts, double and multiple images, unwanted signal attenuation, and so on, can arise, but once they become visible in the NMR image, they can be identified and taken care of. The best way to avoid artefacts is proper design of the pulse sequence that suppresses motion effects as completely as possible. Figure 33 shows a sequence which exploits the moment formalism explained in Section 5.2 to generate a correct velocity-encoded image. It is one of the simplest of such sequences and goes by the name "flow-compensated, velocity-encoding, imaging sequence". The meaning of this seemingly paradoxical name is the wish to introduce velocity encoding only in the direction in which it is desired (say, along the main axis of motion), but to suppress unwanted artefacts due to motion which might affect the image quality.

Relating to the moments discussion, the following requirements must be met in the sequence of Figure 33: $\boldsymbol{m}_0 \neq 0$, $\boldsymbol{m}_1 = 0$ in phase direction — the position encoding should be preserved, but it must be insensitive to motion — realized by a pair of rectangular gradients with equal duration and intensity ratio 3:1.

$\boldsymbol{m}_0 = 0$, $\boldsymbol{m}_1 = 0$ in slice direction — the gradient should excite a slice but leave no residual phase shift depending on either position or velocity — realized by a pair of negative lobes on both sides of the actual slice gradient with same total duration but one-third of the slice gradient strength.

$\boldsymbol{m}_0 = 0$, $\boldsymbol{m}_1 = 0$ in read (frequency-encoding) direction — these conditions can only be met for the center of the acquisition window. While $\boldsymbol{m}_0 \neq 0$ before and after this echo, so that position encoding is actually possible at all, it is unavoidable to have $\boldsymbol{m}_1 \neq 0$ during the same period because the evolution of the phase under the gradient is determined. By rendering $\boldsymbol{m}_1 = 0$ at the time of the echo, the influence of velocity on the signal is minimized, but in general the read direction will always be the one which is most severely affected by motion. Note that higher orders of motion can also be compensated if the gradient pulse trains fulfill conditions such as $\boldsymbol{m}_2 = 0$ and so on, at the cost of more complicated and longer encoding schemes (see [42] for a useful overview).

In order to actually generate a velocity image, in addition to the compensated phase, slice, and read gradients, a gradient pair is introduced which has the purpose of encoding velocity. It can be applied in any of the three directions, and at any time within the sequence. However, practical experience — or a thorough computation of the combined effect of all applied gradients, as well as the often unavoidable background gradients and susceptibility effects — suggests short and symmetric sequences, with the flow-encoding direction coincident with the phase-encoding direction if image *and* flow information is to be encoded along the same direction, and read gradients along the direction of slowest motion. The best solution for a particular application cannot be given in general and will

depend on many factors such as field strength, available hardware, sample shape and material, magnitude of velocities, and many more.

Figure 33 contains all that is necessary to generate a three-dimensional image with a three-dimensional velocity field overlaid on it. The actual way in which this image is generated depends somewhat on the expected result, primarily on the range of velocities.

Velocity information is brought into the signal by the bipolar encoding gradient via a phase shift according to Equation 19. If one were satisfied with the measure of an average velocity in a pixel (or there is reason to assume that velocities within one pixel do not vary much), one can use this phase shift directly and translate it into velocities with the proportionality $\phi(\boldsymbol{v}) = 2\pi \boldsymbol{q} \cdot \boldsymbol{v} \Delta$. (Note that instead of displacements, the result is expressed in terms of velocities, which is fully equivalent, provided that velocities within the pixel do not change significantly during the encoding time Δ.) However, since the image-reconstruction process itself also relies on phase information, the bipolar velocity-encoding gradient just adds an extra contribution that cannot easily be separated from the phase shifts resulting from the imaging gradients. The solution is to acquire two images: one with and one without ($\boldsymbol{q} = 0$) the velocity-encoding gradient. Both images are processed, and the phases in each pixel are computed; because the signal is complex, the phase angle is given by $\varphi = \tan^{-1}[Im(S)/Re(S)]$, where *Im* and *Re* denote the imaginary and the real part of the signal, respectively. One can then subtract the phases of each pixel, and the difference directly renders the velocity in that pixel. In a real experiment, imperfect field and gradient distributions and local susceptibility variations can, and usually will, give rise to uncontrollable shifts of the reference phase, which are eliminated by this subtraction procedure as well.

The result of such a procedure contains the information of the spin density of the object and the average velocity per pixel in one direction. One can simply repeat the experiment with the vector $\boldsymbol{q}$ aligned in the other two orthogonal directions and obtain a set of data that can be used to reconstruct a vector plot, where each vector contains all velocity components in each pixel. Because of the reference measurement, four individual experiments are needed to achieve this. However, the flow field of interest is often described sufficiently by certain components of the velocity, or by two-dimensional images corresponding to selected slices of the object. Two examples of vector plots in quite different situations — internal circulation in water drops and gas flow around an obstacle — are shown in Figure 34.

Whenever a finite *velocity distribution* within a pixel is suspected, the propagator can be obtained by using the same pulse sequence, but varying the magnitude of the velocity-encoding wave vector in full analogy to the measurement of the pure, spatially unresolved propagator described in Section 5.2. This case is shown in Figure 33, where the diagonal lines in the flow-encoding gradient symbolize repeated application with different values. As in all propagator and velocity encoding experiments, the range of gradients must be considered. In complete analogy to encoding of position (Eq. 13), the range of velocities covered, also called field of flow (FOF), is given by:

$$\mathrm{FOF} = \frac{n-1}{2} \frac{2\pi}{\gamma g_{\max} \delta \Delta} \tag{29}$$

Like in imaging, aliasing can occur if velocities outside the FOF exist. For measurements of average velocities, the same condition holds if the total phase shift due to velocity exceeds 2π. For velocity fields of simple structure, this problem can be accounted for by so-called unwrapping algorithms.

5.4. Time-of-Flight Methods

For high velocities and displacements exceeding one pixel, or in general for situations where the visualization of flow and obstructions is more relevant than a quantitative evaluation, a number of quite different experiments have been designed that are based on a time lag between excitation and image acquisition, commonly known as time-of-flight methods.

Several methods exploit the transport of spins or dopants into or out of the image volume to derive a measure of velocities. For instance, if an image is recorded in a particular slice of the excitation volume of the resonator by using a slice-selective rf pulse, fluid leaving this slice during the pulse sequence before acquisition will lead

Figure 34. A) Vector plot of velocities inside a water drop falling in air [55]. Each individual encoding step was applied to a different drop, with drops triggering the acquisition time by passing a light gate. Care was taken to ensure that all drops were identical in size and motion, thereby allowing the reconstruction of an average flow pattern. The vortex structure of the internal motion, driven by air friction, is clearly visible. The drop was falling at 2 m/s, and maximum internal velocities were on the order of ± 0.2 m/s. B) Vector plot of gas flow around a 10 mm diameter solid sphere. For this experiment, the signal from hyperpolarized ^{129}Xe nuclei in a gas mixture was used; the maximum gas velocity was 180 mm/s.

to a loss of signal intensity, as fresh fluid that enters into this slice has not been encoded by the pulse sequence. This approach is often used in angiography, the medical discipline of monitoring blood transport in vessels, and is known as artery spin labeling (ALS). Another possibility is the addition of a tracer substance that has an effect on NMR parameters, for instance, a paramagnetic complex that reduces relaxation times when dissolved in water. The spatial distribution of relaxation times determined in a T_1 or T_2 parameter image allows the reconstruction of the transport properties of the tracer in a series of images. The technique is thus favorable for slow transport processes on timescales of seconds to hours, or for qualitative visualizations where the main objective is to detect the presence of the tracers in part of the sample.

A related strategy is introduced by so-called tagging or, more generally speaking, time-of-flight experiments. The tagging technique is a different approach to determining velocities in a moving object. It is often used for visualization, but can also be extended to provide quantitative information about flow fields. The principle consists of "tagging", or labeling, a certain region of the sample by manipulating the magnetization inside this volume and acquiring the image after some delay during which the labeled volume is deformed. For flow systems with time-invariant flow patterns, movies can be reconstructed from a series of such images with different delay periods. A simple realization is the tagging of a single slice, which is achieved by applying a soft pulse in the presence of a pulsed field gradient, exactly as described in Section 2.3 for slice selection. This slice can be "dark", that is, the spins in the slice are saturated by the rf pulse and the subsequent imaging sequence generates an image of the total volume minus the saturated spins, which show up as a dark stripe. Figure 35 shows one possibility of what such a pulse sequence can look like, and snapshots for flow of a fluid through a fixed bed of catalyst containing pellets are presented as an example for this method. By applying the slice-selective pulse at a different position within the sequence, or simply by subtracting the image from a reference spin-density image acquired without a tagging element, images can be obtained which highlight the moving volume in front of a dark background, as has been done in this example.

A tagging experiment often makes complicated motion more readily accessible for the ex-

Figure 35. A) Single-slice tagging sequence. The 90° soft pulse in the presence of a magnetic field gradient excites the magnetization inside a slice and transfers it to the transverse plane. The subsequent so-called spoiler gradients destroy any coherence of this magnetization so that it will not contribute to the signal later on in the sequence (the spoiler gradients are drawn in three orthogonal directions, but a single direction is often sufficient). The following imaging sequence acquires a signal of the whole object with the exception of the spins inside the slice that was excited in the beginning and that has been deformed due to motion during the waiting time Δ; a single black stripe inside an otherwise undisturbed image is observed. B) Tagging of water flow in a bed packed with 7 mm diameter beads. The width of the grid line is 2 mm. The evolution time varied τ varied between 0 and 500 ms. The volume flow rate is 2.93 mm^3/s, and the spatial resolution 195 × 390 mm. Each image is the result of a tagging experiment with a given evolution time which has been subtracted from a reference frame to highlight the deformed slice. (Reproduced from [56] with permission).

perimenter, but is limited to displacements exceeding the image resolution, or when fast image acquisition of the flow phenomenon is needed. The ultimate time limit, for phase encoding and for tagging, is the longitudinal relaxation time of typically a few seconds in liquids; if it is much exceeded, the information encoded into the spin system is lost, or — for tagging — the contrast between tagged spins and the environment has disappeared. For an additional overview of motion measurements in industrial applications, see [24, 56 – 59].

6. Hardware and Materials

6.1. Imaging and Micro-Imaging Hardware

It is not the purpose of this article to provide a complete list of NMR imaging equipment and manufacturers. However, some general remarks can be given that allow the reader to assess the feasibility of studying a particular problem.

Some main features that need to be discussed in the context of NMR imaging are sample dimensions; magnetic field strengths; field homogeneities; rf and gradient capabilities; and data acquisition, storage, and processing properties.

The first concern of the user is certainly the shape and size of the sample. Because of the need to generate homogeneous magnetic fields for the majority of studies, the object of interest usually has to be surrounded by the magnet. Solenoid coils provide a maximum of field homogeneity, but the final optimization is achieved by so-called shim systems, resistive coils wound in particular patterns to generate magnetic field corrections up to fourth or fifth order when the field dependence is expressed in a Taylor series expansion relative to the spatial coordinates. The larger the sample volume, the more correction coils are required to achieve a "flat" field distribution, but the extreme degree of homogeneity used in spectroscopy for samples of only some millimeters in diameter cannot be obtained in an imaging environment.

Imaging systems can often be attributed to one of two standard basic setups. On the one hand, whole-body systems employed in medical diagnostics for human patients have the largest available volumes; on the other hand, standard superconducting magnets produced for spectroscopy are frequently used for microimaging purposes, leaving diameters of a few centimeters for the sample. In between, dedicated magnets of typically 10 – 20 cm accessible diameter are also available that serve the purpose of animal studies.

Spatial resolution usually goes along with sample, or rather resonator, dimensions. Considering the experimental time required for repeated phase encoding, a rule of thumb says that the resolution is about 1/100 of the total dimension. That, in turn, means that ever stronger gradients are required if one wants to reach this resolution limit in small samples. On the other hand, because gradient coils also need to enclose the whole sample, the total power consumption grows drastically towards large-object imaging. For example, typical maximum gradient strengths for medical scanners are 30 – 50 mT/m at currents of several hundred amperes, while a standard microimaging system works at 1 – 2 T/m with a current of 50 A. For true microscopic resolution, several tens of teslas per meter are applied in gradient coils of much smaller dimensions. Total signal intensity and heating effects are some of the limits at the small scale. Note that it is often not the maximum gradient strength itself, but the capability of switching gradient currents in a fast and reproducible way, that determines the feasibility of fast and multiscan experiments.

The magnetic field strength is the other main characteristic of the NMR apparatus. In general, high fields are desired because of their direct influence on the signal-to-noise ratio (exceptions are samples with high internal susceptibility gradients, where low fields can possess advantages), but they generally come at higher costs. Again, one frequently relies on standard magnetic fields that are commercially available — between 1 and 4 T for medical imaging (a range of systems working at lower field have been developed recently), and between 4.7 T and 18 T for standard laboratory magnets, corresponding to ^{1}H Larmor frequencies between 200 and 750 MHz.

One further topic of NMR experiments is the capability of rf generation as well as the data acquisition parameters. Since the requirements for multidimensional NMR spectroscopy (multichannel pulse generation; precise reproducibility of frequencies, phases, amplitudes, and times; digital control over pulse shapes and bandwidth) are usually far more demanding, MRI equipment has benefited considerably from developments in the spectroscopy sector. Likewise, fast data acquisition and on-line image reconstruction have become routine aspects due to the need to optimize clinical scan parameters by immediate verification of the imaging quality.

In recent years, a growing number of low-field devices based on electromagnets or permanent magnets have been developed that meet two common goals: to reduce cost and thus make available imaging systems for the nonspecial-

ist and for routine applications, and to bring the sensor to the object in order to increase flexibility and provide in-line or on-line capabilities in production processes. Of course, this approach comes at a price (e.g., reduced sensitivity and field homogeneity), but imaging, particularly of ^{1}H-containing substances, is still feasible within timescales comparable to high-field devices because, once the signal-to-noise ratio remains above a certain level, the experimental time is limited only by the spatial resolution but not by the number of accumulations. The decrease of T_1 with lower field strength that is observed for many types of samples (except free liquids) is actually of advantage for performing faster experiments. Several types of these systems are currently becoming commercially available.

Apart from classical imaging systems, i.e., magnets with relatively homogeneous fields with defined triaxial gradients [60, 61], a number of alternative approaches have been developed that allow the acquisition of pointwise information or the scanning of objects with 1D or 2D resolution. These can be of considerable advantage whenever the full 3D contrast information is not required, for instance, in monitoring of local relaxation parameters or depth-dependent profiling. The main advantage of these scanners is their high flexibility in obtaining NMR information on surfaces and extended objects in arbitrary places, making use of the portability of the complete system consisting of the sensor and the amplifier/acquisition/analysis unit [62, 63].

6.2. Imaging X Nuclei

Imaging of protons represents the majority of all MRI applications. This is mostly due to the high sensitivity of the ^{1}H nucleus, which has the largest gyromagnetic ratio among all stable isotopes, but also because of its ubiquity in most systems of interest, both medical and nonmedical. However, other nuclei are of substantial interest, mostly because their visualization is more specific, or because these are more sensitive as tracers for their local environment. For example, ^{1}H has one of the smallest ranges of chemical shifts, and ^{13}C chemical shift imaging is much more suitable for generating distribution maps of individual substances. Imaging, with its requirements of extended measurement time, depends on the abundance and receptivity of the NMR-active nuclei much more than conventional spectroscopy. For instance, quadrupolar nuclei with intrinsically large line widths and short T_2 often cannot be used in time-consuming imaging sequences, for example, if long echo times are involved. The discussion in → Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy retains its validity, but the number of technically useful nuclei in imaging is smaller. Table 1 summarizes the most important isotopes for NMR imaging.

Despite the low sensitivity to many X nuclei, the principle of NMR imaging remains unchanged, so that discussion of this topic is intentionally kept short. However, it must be stressed that the disadvantage of weak signal is often compensated by the gain in information, and a number of tools are available to increase the sensitivity towards X nuclei substantially. One possibility is the hyperpolarization technique, which mostly applies to gases (see Section 6.3). Many more possibilities are obtained by borrowing strategies known from NMR spectroscopy that are used to transfer polarization from abundant to rare nuclei. For instance, polarization is transferred from ^{1}H to X nuclei, from X to ^{1}H (where the detection sensitivity is higher), or in a cyclic way from ^{1}H to X and back to ^{1}H. Techniques known as DEPT, [65] INEPT, and HMQC not only increase the signal intensity of, for example, ^{13}C nuclei, but also enhance the selectivity, because polarization transfer is achieved only for proton-bound carbon atoms. In addition, less specific transfer sequences exist, all having in common a carefully timed and balanced series of rf pulses on at least two separate frequency channels, this being the minimum hardware requirement for this type of signal enhancement of X nuclei.

Other approaches that currently are gaining increasing importance are based on the transfer of polarization from a suitable molecule or a radical to the nuclei of interest, where the polarization lifetime and efficient transfer are the main problems to be overcome. However, it has even become possible to apply para-hydrogen-induced polarization (PHIP) [66] to in vivo angiography by transferring the PHIP polarization to ^{13}C of a tracer molecule which was subsequently injected into the bloodstream

Table 1. The most important nuclei used in NMR imaging. Larmor frequencies are given for a typical magnetic field strength of modern spectrometers. The molar receptivity relative to ^{1}H assumes equal numbers of nuclei; it is multiplied by the natural abundance to obtain the corresponding receptivity; the numbers assume thermal equilibrium. Isotopic enrichment is routinely applied for studies of ^{2}H, ^{13}C, and ^{17}O, but is also common for ^{3}He and ^{129}Xe. The latter two nuclei are marked in gray to indicate that they are candidates for imaging experiments in the hyperpolarized state. Under these circumstances, their signal strength can be several orders larger than their thermal receptivities. (Values taken from [64])

Isotope	Spin	Natural abundance, %	Larmor frequency at 11.7 T, MHz	Molar receptivity	Receptivity at natural abundance
^{1}H	1/2	99.988	500	1	1
^{2}H	1	0.012	76.75	9.6×10^{-3}	1.1×10^{-6}
^{3}He	1/2	1.4×10^{-4}	380.90	0.44	6.2×10^{-5}
^{13}C	1/2	1.07	125.73	1.6×10^{-2}	1.7×10^{-4}
^{17}O	5/2	0.038	67.78	2.9×10^{-2}	1.1×10^{-5}
^{19}F	1/2	100	470.47	0.83	0.83
^{23}Na	3/2	100	132.26	9.3×10^{-2}	9.3×10^{-2}
^{31}P	1/2	100	202.40	6.7×10^{-2}	6.7×10^{-2}
^{129}Xe	1/2	26.4	139.05	2.2×10^{-2}	5.7×10^{-3}

[67]. Dynamic nuclear polarization (DNP), that is, the transfer of electron magnetization to nuclei via stable radicals introduced into the sample, is developing into a routine method as problems with fast sample heating and transport have been overcome. It requires transfer of polarization from unpaired electrons to nuclei in the solid (usually low-temperature) phase and subsequent heating preserving the nuclear states sufficiently long for performing single-scan experiments with dramatic increase in sensitivity [68].

6.3. Liquids, Solids, and Gases

Most imaging sequences — including those presented in this contribution — are designed for liquids or soft matter with their favorable properties such as relatively long T_2 and moderate T_1 relaxation times. However, solids are also of substantial interest, for example, in materials research. Dedicated methods such as single-point imaging are often the only way to enable imaging of solids. For samples with slightly longer transverse relaxation times, echo methods or frequency encoding and backprojection techniques represent another possibility.

The situation is somewhat different for gases. Depending on the mechanism of relaxation, either very short or very long relaxation times are observed. In monatomic noble gases, relaxation times can be on the order of minutes to hours and depend strongly on the presence of other nuclei or surfaces that serve as relaxation sinks. While this appears particularly suitable for the implementation of multi-echo sequences, the large diffusivity of gases severely restricts the use of pulsed field gradients because they lead to an irreversible loss of coherence. Therefore, again, position encoding must be performed on a short timescale, and to overcome the long longitudinal relaxation times, small flip angles such as in FLASH, are often required. The extraordinary advantage of noble gases due to their low relaxivity, however, is the possibility to polarize them almost to the theoretical maximum in a process called hyperpolarization [69]; ^{129}Xe and ^{3}He have been used extensively for these purposes, and polarization equipment has meanwhile become available commercially. For combining hyperpolarization techniques with measurements of transport, see Figure 34b.

Polyatomic gases — most importantly hydrocarbons or fluorinated gases, which are of particular importance due to their high density and the natural contrast in a fluorine-free environment— have a different relaxation mechanism, and values of T_1 and T_2 are in the range of only a few milliseconds or less. With the opposite argument to monatomic gases, this leads to the considerable advantage of rapid repetition times so that multi-echo sequences are replaced by a series of individual phase- and frequency-encoded sequences. This property compensates, to a certain degree, the disadvantages brought about by a spin density which is orders of magnitude lower than that of liquids.

The radial-flow packed-bed reactor is a design with very small pressure drop and most suitable for large-capacity plants. It has replaced the axial-flow reactor for several important chemical processes such as ammonia synthesis, ethylbenzene dehydrogenation, and catalytic reforming. The design of a radial-flow reactor is more complicated than that of an axial-flow reactor; it must deal with several unique concerns: flow distribution along the length of the reactor, thermal reaction in the void space, catalyst settling, and expansion and contraction of the catalyst basket. The successful operation of a commercial radial-flow reactor lies mainly in the details of the mechanical design.

1. Introduction

Radial-flow packed-bed reactors are used to carry out several important, large-scale catalytic chemical reactions in the petroleum and chemical industries, such as ammonia synthesis, methanol synthesis, catalytic reforming, and dehydrogenation of ethylbenzene to styrene.

Figure 1 shows how radial-flow reactors differ from the more commonly used axial-flow reactors. In an axial-flow reactor, the feed enters at one end of the reactor, flows across the catalyst bed in the direction along the axis of the reactor, and exits from the other end. In a radial-flow reactor, the feed is distributed along the length of the reactor, and flows in the radial direction across the catalyst bed contained between two perforated concentric screens (the screen assembly that contains the catalyst is commonly called a basket). The reactant may flow from the center toward the outer annulus of the reactor or from the outer annulus toward the center of the reactor. In a Z-shaped radial-flow reactor, the feed and the effluent flow in the same direction in the center pipe and the annulus; in a Π-shaped reactor, the feed and the effluent move in the opposite directions. As discussed in Chapter 4, different flow arrangements—inward versus outward flow and Z-shaped versus Π-shaped—have been used for commercial reactor designs.

Figure 1. Axial- versus radial-flow reactors. a) Axial-flow reactor; b) Z-shaped radial-flow reactor; c) ?Π-shaped radial-flow reactor

Radial-flow reactors were developed to replace axial-flow reactors for large-scale chemical plants in the late 1960s and early 1970s [1 – 7]. As the plant capacity increases, the diameter of an axial-flow reactor must be increased in order to maintain the same pressure drop across the catalyst bed. With a larger diame-

ter, the reactor shell becomes thicker, heavier, and more expensive to fabricate. Besides, the diameter of the reactor is limited by the capabilities of fabrication and transportation facilities. Above some plant size, single axial-flow reactors become impractically large, and multiple reactors in parallel become necessary. In contrast, a radial-flow reactor can be scaled up by increasing the length instead of the diameter. Furthermore, since in a radial-flow reactor the reactant is fed along the length of the reactor, a larger cross-sectional area is available for the flow and the catalyst bed is shallower; as a result, the pressure drop across a radial-flow catalyst bed is much less than that across an axial-flow catalyst bed.

An example of the pressure-drop advantage of a radial-flow reactor over an axial-flow reactor is shown in Table 1. For a 1500 t/d ammonia plant, the pressure drop across the catalyst beds of a radial-flow reactor is only 0.2 kg/cm^2 versus 12 kg/cm^2 across those of an axial-flow reactor, and the power consumption of the synthesis loop with a radial-flow reactor is 64 % of that with an axial-flow reactor. Many old ammonia plants were retrofitted with radial-flow catalyst beds to increase plant capacity and reduce energy consumption [9 – 11]. Because the pressure drop across the radial-flow reactor is very small, this change also allows a reduction in catalyst particle size from 6–10 mm to 1.5–3.0 mm to increase catalyst productivity. The catalyst effectiveness factor is reported to be at least 0.9 for 1.5 mm ammonia catalyst versus approximately 0.6 for 5.7 mm catalyst [12]. The catalyst volume can be reduced by 27 % if 2 mm catalyst particles are used for ammonia synthesis instead of 10 mm catalyst particles [3].

The design of the radial-flow reactor is more complicated than that of the axial-flow reactor because of several unique concerns. First, to achieve good conversion, the flow must be distributed uniformly along the length of the reactor. Second, catalyst settling over time will create a void at the top of a radial catalyst bed which, if not blocked, will allow flow bypassing. Depending on the mechanical properties of the catalyst and the frequency of reactor startup and shutdown, 5–15 % of extra catalyst is normally loaded in a radial-flow reactor to allow for settling. Third, compared with an axial-flow reactor, a radial-flow reactor requires additional void space (i.e., space not occupied by catalyst) for distributing flow along the length of the reactor. For some high-temperature reactions such as dehydrogenation of ethylbenzene to styrene, the thermal reactions taking place in the void are less selective than the catalytic reactions. To minimize the yield loss caused by the thermal reactions, commercial styrene reactors typically have a displacement cylinder in the center pipe to reduce the void volume. Finally, the perforated screens containing the catalyst must be designed to withstand the thermal stresses that develop with each startup and shutdown, especially during emergency shutdowns when large temperature differences may develop between the inner and outer screens.

Radial-flow catalyst beds may be susceptible to channeling under some low-flow conditions because pressure drops are too low to distribute the feed gas properly. A problem encountered in ammonia plants is the initial activation of the ammonia synthesis catalyst. Since at startup there is no heat of reaction, synthesis gas is heated in a startup heater and circulated through the ammonia reactor to reduce the catalyst. Unless the startup heater is very large, the gas velocity during startup is much lower than during normal operation. At such an extremely low velocity it is difficult to obtain uniform flow through the catalyst bed. Ideally, to avoid water damage to the catalyst that has already been reduced to free iron, catalyst reduction should proceed in a plug-flow manner, i.e., once the gas has picked up water vapor from catalyst reduction, it should pass only the catalyst that is still in oxidized state. Prereduced catalysts have been used in some radial-flow ammonia reactors because of concerns over flow channeling during startup [13].

2. Applications of Radial-Flow Reactors

The physical dimensions and operating conditions of several commercial radial-flow reactors are presented in Table 2. Illustrated in Figures 2,3, 4 and 5 are radial-flow reactor designs for ammonia synthesis, ethylbenzene dehydrogenation, and catalytic reforming.

Synthesis of ammonia from hydrogen and nitrogen (→ Ammonia) is an exothermic reaction, and is usually carried out at 400–500 °C and

14–21 MPa. The ammonia concentration in the reactor effluent is 12–22 %, which results in a large amount of the synthesis gases being recycled. Because the radial-flow reactor has a much smaller pressure drop, choosing a radial-flow reactor over an axial-flow reactor can reduce the size of the recycle gas compressor and allow use of smaller catalyst particles to improve the catalyst efficiency. Major ammonia technology licensors, Kellogg Brown & Root (KBR), Topsøe, Uhde, and Ammonia Casale, have developed their own proprietary radial-flow reactor designs [14 – 21]. Figure 2 shows KBR's Advanced Ammonia Process converter design. It has four catalyst beds in one shell, and three interstage coolers to remove the heat of reaction from the effluents of beds 1–3. In all four beds, the gas flows from outside to inside. In the upper three beds, the gas flows downward in the outer annulus and upward in the inner annulus (i.e., Π-shaped catalyst bed). After it comes out of the inner annulus, the gas turns downward to pass through the shell side of the interstage cooler. In the bottom bed, the gas flows downward in both the outer annulus and the center pipe (i.e., Z-shaped catalyst bed). Another radial-flow reactor design for ammonia synthesis, the Topsøe S-200 type converter, is illustrated in Figure 3. It has two catalyst beds and two internal heat exchangers: one at the bottom of the reactor and the other in the center core of the lower catalyst bed. The cold reactor feed first flows down the annulus between the reactor shell and the shell containing the catalyst bed. There is a large pressure difference but a small temperature difference across the reactor shell, and a small pressure difference but a large temperature difference across the catalyst bed shell. The feed is heated in the bottom heat exchanger by the effluent from the upper bed (the second catalyst bed). It then mixes with a cold bypass and with a second feed stream, which is heated in the interbed heat exchanger by the first bed effluent. The mixed feed flows from the annulus toward the center of the first catalyst bed. After passing through the shell side of the interbed exchanger, the first-bed effluent flows outward across the second catalyst bed, and then exits through an annulus and the bottom heat exchanger. The first catalyst bed has inward flow, while the second catalyst bed has outward flow. Both catalyst beds are Π-shaped.

Figure 2. KAAP ammonia converter [14]

Dehydrogenation of ethylbenzene to styrene (→ Styrene) is an endothermic reaction. It is carried out with steam dilution at 540–650 °C and under low positive pressure or vacuum. The reaction is limited by thermodynamic equilibrium, and the reactant must be reheated between the catalyst beds in order to achieve 60–70 % per-pass conversion. Commercial styrene plants typically have two or three catalyst beds in series, each contained in individual vessels, with external or internal interstage reheaters. Both the conversion and selectivity are favored by lower pressure. Radial-flow reactors are used for ethylbenzene dehydrogenation because their smaller pressure drops allow the reactors to operate at a lower pressure than axial-flow reactors. Figure 4 shows a typical commercial styrene reactor design. In this design, the reactant flows from the central core toward the outer annulus. Since the reaction takes place under vacuum, the volume of the gas flow increases significantly as it moves across the catalyst bed. The outward flow arrangement provides a larger cross-sectional area toward the outlet of the catalyst bed as the gas volume increases. Many commercial styrene reactors have a displacement cylinder in the central core to reduce the void volume [22]. At temperatures above 540 °C, a small amount of ethylbenzene is dehydrogenated to styrene even in the absence of catalyst, but the thermal reaction has a lower selectivity to styrene than the catalytic reaction. Therefore it is desirable to minimize the void volume to improve the selectivity to styrene.

Catalytic reforming is an important refining process for upgrading the octane number of naphtha for gasoline blending. It is also a major process for production of benzene, toluene, and xylenes for the petrochemical industry. In reforming, molecules are rearranged, or reformed, without changing their carbon numbers. Several reactions take place in catalytic reforming: dehydrogenation, isomerization, dehydrocyclization, and hydrocracking. The net effect of the reforming reactions is endothermic. The reaction temperature is in the range of 430–540 °C. The reaction pressure used to be above 2.8 MPa in order to control catalyst deactivation caused by coking. With more stable catalysts and continuous catalyst regeneration, the newer generation of reformers operates below 700 kPa. The reformer feed is a mixture of naphtha and hydrogen. Radial-flow reactors are used for catalytic reforming to reduce the pressure drop and thus the size of the hydrogen recycle compressor. Three or four reactors operate in series with external heaters in between; the reactors may stand alone or stack up [24 – 28]. Figure 5 shows a radial-flow, moving-bed reactor design developed by UOP for the CCR Platforming Process [27]. The catalyst moves slowly downward in

Figure 5. UOP radial-flow moving-bed reactor [27] a) Catalyst transfer pipe; b) Catalyst basket; c) Catalyst; d) Catalyst basket; e) Interstage heater; f) Interstage heater; g) Catalyst outlet [27]

the space contained between the outer and inner screens of the reactors, and through the pipes between the reactors. The catalyst coming out of the bottom reactor is lifted to the regenera-

tor and returned to the top reactor. The reactants flow from the outer annulus toward the center pipe, go out from the center pipe to the external heater, and return to the outer annulus of the reactor below. As the reactants move from one reactor to the other, the reaction rates become slower. To compensate for the slower reaction rates, the reactors become progressively larger, with the first reactor being the smallest and the last reactor the largest. In Figure 5, the effluent leaves the bottom of the center pipe. Since late 1980s, UOP has changed the design so that the effluent exits from the top of the center pipe, i.e., the catalyst bed configuration was changed from Z-shape to Π-shape [28]. As discussed in Chapter 4 this change improves the vapor distribution along the length of the catalyst bed.

UOP also developed similar radial-flow, moving-bed reactor designs for the dehydrogenation of propane to propylene (Oleflex Process) and the conversion of liquefied petroleum gas to aromatics (Cyclar Process).

3. Design of Commercial Radial-Flow Reactors

Many studies have been published in the literature on a wide range of subjects concerning radial-flow reactor design such as pressure drop [29], flow distribution [30 – 37], heat transfer in the radial direction [38], and effects of flow distribution and flow direction on conversion and selectivity [39 – 46]. The rigorous analyses and complex mathematical models presented in those publications are rarely used for commercial radial-flow reactor design. Reaction rates in most commercial radial-flow reactors are controlled by thermodynamic equilibrium. For these reactors, flow direction and axial and radial dispersions have small effects on conversion and selectivity. Pressure drops used for commercial radial-flow reactor design, in many cases, are empirical numbers derived from field data rather than from laboratory results. As explained in 5, the pressure drop increases over time as the reactor goes through startup and shutdown cycles.

Most problems with commercial radial-flow reactors are due to faulty mechanical design; they are not caused by lack of thermodynamic or kinetic data or inaccurate mathematical modeling. Many factors must be considered for the mechanical design of a commercial reactor: materials of construction, fabrication, transport, field erection, corrosion, thermal stresses, catalyst loading and unloading, and maintenance and repair of internal heat exchangers and catalyst basket screens. Case studies on the design and operation of commercial reactors have been published in *Ammonia Plant Safety*. Three subjects unique to radial-flow reactor design are discussed below: flow distribution along the length of the catalyst bed, catalyst basket design, and catalyst settling.

4. Flow Distribution

The principle governing the flow distribution in a radial-flow reactor is the same as that used for designs of sprayers for irrigation, pipe burners for gas fuel, diffusers for disposing of wastewater under sea, and air distributors for gas-turbine combustors. The basic unit of all these devices is a pipe with holes drilled through its wall (commonly referred to as a "manifold"): fluid may be collected from or distributed to the surroundings through the perforated wall. The fluid flow in a manifold may be described by a general form of the Bernoulli equation:

$$(1/\rho)\,\mathrm{d}P/\mathrm{d}Z+\kappa\,\mathrm{d}\left(U^2\right)/\mathrm{d}Z+\lambda\,(1/D)\left(U^2/2\right)=0 \tag{1}$$

where ρ is the density of the fluid, κ the kinetic energy coefficient (0.5 for pipe with a solid wall), and λ the friction factor. When a fluid moves along a manifold, its axial velocity changes as a result of the subtraction or addition of the side stream through the holes. If the friction loss is negligible, the pressure rises when the velocity decreases (loss in kinetic energy), and falls when the velocity increases (gain in kinetic energy). In contrast, friction always causes the pressure to decrease, regardless of whether the velocity increases or decreases.

In a manifold distributing fluid to the surroundings, if the influence of the kinetic energy is greater than that of the friction loss (e.g., a short manifold with a small length-to-diameter ratio), the pressure increases along the length of the manifold and more fluid is distributed toward the end of the manifold. Conversely, if the influence of the kinetic energy is smaller than

that of the friction loss (e.g., a long manifold with a large length-to-diameter ratio), the pressure decreases along the manifold and more fluid is distributed near the entrance of the manifold. Thus, one possible way to control the flow distribution is to vary the length-to-diameter ratio of a manifold, balancing the kinetic energy gain with the friction loss. Another way is to increase the resistance to the sidestream by decreasing the open area of the holes. As a rule of thumb, a uniform flow distribution can be obtained if the resistance to the sidestream is ten times or greater than the initial kinetic energy in the manifold. A third way to control the flow distribution is to vary the distribution of the holes. For example, placing more holes near the end of a slender manifold helps make the flow distribution more uniform.

In a manifold collecting fluid from the surroundings, the pressure always decreases toward the exit because of the friction loss and the gain in kinetic energy. Possible options to ensure a uniform flow distribution in a collecting manifold include increasing the resistance against the side stream and placing fewer holes near the exit.

In a radial-flow reactor the flow distribution is governed by the pressure profiles in the center pipe and the outer annulus and the resistance across the catalyst bed. Two separate equations can be written to describe the fluid flow in the center pipe and the outer annulus:

$$(1/\rho_{\mathrm{i}})\,\mathrm{d}P_{\mathrm{i}}/\mathrm{d}Z+\kappa_{\mathrm{i}}\,\mathrm{d}\left(U_{\mathrm{i}}^{2}\right)/\mathrm{d}Z+\lambda_{i}\,(1/D_{\mathrm{i}})\left(U_{\mathrm{i}}^{2}/2\right)=0 \tag{2}$$

$$(1/\rho_{\mathrm{o}})\,\mathrm{d}P_{\mathrm{o}}/\mathrm{d}Z+\kappa_{\mathrm{o}}\,\mathrm{d}\left(U_{\mathrm{o}}^{2}\right)/\mathrm{d}Z+\lambda_{\mathrm{o}}\,(1/D_{\mathrm{o}})\left(U_{\mathrm{o}}^{2}/2\right)=0 \tag{3}$$

where the subscript i refers to the center pipe, and o to the outer annulus. The difference between the pressures in the center pipe and the outer annulus is equal to the sum of the pressure drops across the inner screen, the catalyst bed, and the outer screen:

$$P_{\mathrm{i}}-P_{\mathrm{o}}=\Delta P_{\mathrm{i}}+\Delta P_{\mathrm{b}}+\Delta P_{\mathrm{o}}. \tag{4}$$

The pressure drops across the inner and outer screens can be calculated from the screen resistance coefficient ξ and the radial velocity, which varies from V_{i} to V_{o} across the catalyst bed:

$$\Delta P_{\mathrm{i}}=(\xi_{\mathrm{i}})\,(\rho/2)\,(V_{\mathrm{i}}/\Phi_{\mathrm{i}})^{2} \tag{5}$$

$$\Delta P_{\mathrm{o}}=(\xi_{\mathrm{o}})\,(\rho/2)\,(V_{\mathrm{o}}/\Phi_{\mathrm{o}})^{2} \tag{6}$$

where Φ_{i} and Φ_{o} are the void fractions of the inner and outer screens, respectively. The kinetic energy of the radial flow can be represented with the general form of the Bernoulli equation:

$$\mathrm{d}\,(P/\rho)\,/\mathrm{d}r+\mathrm{d}\left(V^{2}/2\varepsilon^{2}\right)+\lambda_{\mathrm{b}}\,(1/d_{\mathrm{p}})\left(V^{2}/2\right)(1-\varepsilon)\,/\varepsilon^{3}=0 \tag{7}$$

where ε is the void fraction of the catalyst bed, and λ_{b} is the friction factor of the catalyst bed and can be estimated from the Ergun equation:

$$\lambda_{\mathrm{b}}=150/Re_{\mathrm{p}}+1.75 \tag{8}$$

where Re_{p} is the Reynolds number based on the diameter of the catalyst particle and the local velocity. A computer model needs to be developed to solve all the above equations in order to calculate the flow distribution in a radial-flow reactor. More details are presented in [37].

Figure 6 illustrates how the reactor shape can affect the flow distribution in a radial-flow reactor. For the case that the friction loss controls the change in pressure, a Z-shaped reactor has a more uniform flow distribution than a Π-shaped reactor, because in a Z-shaped reactor the flows in the center pipe and the annulus move in the same direction, and so do the pressure changes. For the case that the kinetic energy predominates, a Π-shaped reactor has a more uniform flow distribution. In a Π-shaped reactor, the flows in the center pipe and the annulus move in opposite directions. If the pressure increases in the annulus because of deceleration, it will decrease in the center pipe because of acceleration. The reverse in flow direction offsets the pressure changes due to deceleration and acceleration, and gives a more uniform flow distribution in a Π-shaped reactor.

As shown in Figure 4, in a styrene reactor the reactant flows from the center pipe toward the annulus. The tapered displacement cylinder in the center pipe reduces the void volume to minimize thermal reactions. It also gradually reduces the cross-sectional area; thus, as the flow decreases along the center pipe, the velocity remains relatively constant, resulting in a flatter pressure profile and a more uniform flow distribution across the catalyst bed. The shape of the displacement cylinder is a variable that can be adjusted to improve the flow distribution in a radial-flow reactor.

To keep the diameter of the reactor shell within fabrication and transportation limits, an approach commonly used in scaling up radial-flow reactors is to increase the length without changing the diameters of the inner and outer screens and the reactor shell. However, as the capacity increases, the velocities in the center pipe and the annulus also increase. This results in steeper pressure profiles in the center pipe and the annulus and consequently a less uniform flow distribution across the catalyst bed. Certain reactor dimensions may need to be adjusted when the reactor design is modified for a greater capacity in order to maintain a uniform flow distribution.

5. Catalyst Basket Design

The screens of the catalyst basket in a radial-flow reactor may be formed with perforated plates or V-shaped "wires" welded circumferentially to supporting bars (commonly referred to by the trade name Johnson screens, see Figure 7). V-shaped or profile wires on Johnson screens are aligned vertically with the slots between them as small as 0.25 mm. This design provides a smooth surface which allows the catalyst to slide up and down without causing abrasion [47]. Perforated plates are expensive to fabricate for large reactors because the plates become too thick, and they have been gradually replaced by Johnson screens. To provide elasticity for thermal expansion, a layer of wire mesh is sometimes overlaid on the side of the perforated plate or the Johnson screen in contact with the catalyst. Outer screens of reformer catalyst baskets are commonly made of screens in a scallop shape [48, 60], which can be installed and repaired as individual pieces and thus more quickly and simply than a single large basket.

The Janssen equation, which was derived to describe the lateral pressure exerted on the wall of a silo [49], can also be applied to calculate the static force on the screens of a radial-flow reactor when the catalyst is initially loaded. As discussed below, the force on the screens becomes more complicated after the reactor goes through thermal cycling with startup and shutdown.

In a silo, the lateral pressure is transmitted to the wall through the interlocking force between the particles and the friction between the particles and the wall. The downward pressure on the bottom of a silo and the lateral pressure on the wall (the pressures in the axial and radial directions, respectively) can be described by the following equations:

$$P_z = (D\rho_b)\left(1-e^{(-4f'KZ/D)}\right) / (4f'K) \quad (9)$$

$$P_r = KP_z = (D\rho_b)\left(1-e^{(-4f'KZ/D)}\right) / (4f'), \quad (10)$$

where D is the diameter of the silo, ρ_b the bulk density of the solid particles, f' the wall friction factor, and Z the depth from the top. The ratio of lateral to downward pressure K is related to the internal friction between the particles; its value has been reported to be between 0.4 and 0.5 for a wide range of solid particles [50, 51].

Unlike in a liquid filled vessel, the downward pressure on the bottom of a silo is less than the weight of the granular material held in the silo. It levels off after the height reaches approximately three times the diameter. Additional weight beyond this height is supported by the friction at the wall. For an incremental depth ΔZ!

incremental friction force at the wall $= \Pi D \Delta Z P_r f\prime$, and

incremental solid weight $= \left(\Pi D^2/4\right) \Delta Z \rho_b$.

Equating the above two equations gives the asymptotic form of the lateral pressure

$$P_r = D\rho_b/4f\prime \quad (11)$$

The same equations developed for a silo can be used to calculate the radial pressure on the screens of a radial-flow reactor by replacing D with $D_o - D_i$. The friction factor depends on the shape of the catalyst and the surface condition of the screen, i.e., perforated wall, Johnson screen, or wire mesh; its value can be found only from experiments. Figure 8 illustrates the radial and tangential pressures on the inner and outer screens of an ammonia catalyst bed immediately after catalyst loading.

The Janssen equation only describes the force on the reactor screens when the catalyst is initially loaded. Additional forces are developed after each reactor startup and shutdown. For example, during the startup of an ammonia reactor, with the gas flowing from the annulus toward the center pipe, the outer screen is heated up first while the inner screen is still cold. As the outer screen is heated, it expands, the width between the inner and the outer screens increases, and the catalyst "settles" to fill the increased width. Because of the massive weight

of the catalyst, it takes several hours to heat up the catalyst and then the inner screen. After the catalyst has settled, the inner screen is finally heated, and it expands to push the catalyst against the outer screen. Thus, following each startup, more catalyst settles, the void above the catalyst bed increases, and greater force is exerted on the catalyst screens. During shutdown, the outer screen is cooled first; it contracts and compresses the catalyst against the inner screen. After both screens are cooled to ambient temperature, although the compressive force decreases, there is a net increase in the force on the screens compared with before the shutdown, because the outer screen contracts more than the inner screen. To avoid excessive stress on the screens, the inlet gas temperature should be increased or decreased slowly during startup or shutdown to minimize the temperature difference between the inner and the outer screens. Unfortunately, the inlet gas temperature often cannot be controlled during an emergency shutdown, and that is when most reactor screen failures happen.

A computer simulation [52] calculated the forces on the screens of an ammonia reactor based on the catalyst weight alone and those developed during normal startup (11 h) and fast startup (2.5 h). On a relative scale, if the force based on the catalyst weight is 1.0, the force resulting from a normal startup is 1.9, and from a fast startup 4.3.

The analysis described above can be applied to other radial-flow reactors. In the case of dehydrogenation of ethylbenzene to styrene, the reactant flows from the center pipe toward the annulus in a radial-flow reactor. During startup the catalyst is compressed first as the inner screen is heated and expands. It later settles when the outer screen is also heated and expands more than the inner screen. The reverse happens during shutdown: the catalyst first settles when the inner screen is cooled down and it is compressed later when the outer screen starts to cool down. This is an inherent feature of radial-flow reactor: differential thermal expansion between the inner and outer screens and the resulting catalyst settling and stress exerted on the screens after each startup and shutdown. The lifetime of catalyst screens depends to a large extent on the frequency of startup and shutdown that the reactor experiences.

Catalyst leakage from an ammonia reactor because the screens were twisted and torn apart, and the modified design of welding a perforated liner of Inconel to the inner side of the center pipe over the Johnson screens were described [53]. A reforming reactor was shut down after the skin thermocouple on the reactor outer shell recorded ca. 560 °C [54]. When the reactor was inspected, a hole was found on the screen and ca. 3.5 m of catalyst was found in the annulus. Because there was little flow at the bottom of the annulus to remove the heat generated from the hydrocracking and demethylation reactions, the temperature rose and triggered the shutdown. The catalyst in the bottom of the reactor was severely coked and fused into a solid mass.

6. Catalyst Settling and Flow Bypassing

Catalyst in a radial-flow reactor settles or slumps (i.e., drops in height) over time. A critical feature in the design of a radial-flow reactor is to prevent bypass at the top of the catalyst bed. Additional catalyst is loaded above the perforated section of the catalyst basket to compensate for catalyst settling and to seal the flow path above the perforation (Fig. 9).

The amount of catalyst needed for settling varies from process to process, and is determined from practical experience. As discussed in 5 , the catalyst settles as a result of the differential thermal expansion between the inner and outer screens of the catalyst basket. Thus, the thermal expansion coefficients of the materials used for the construction of the screens, the operating temperature, the rates of heating and cooling during startups and shutdowns, and the frequency of startups and shutdowns all affect catalyst settling. Loading procedure also affects the catalyst settling. Evenly spreading the catalyst to make the catalyst more densely packed and limiting the height of free fall to avoid breakup of catalyst particles can reduce the settling. Techniques such as dense loading and vibration have been used to pack catalyst more closely to reduce settling [12, 55]. Some catalysts contain volatile components and require special startup and shutdown procedures for conditioning. If proper startup and shutdown procedures are not followed, those components may leach out of the

reactor and cause the catalyst to shrink and drop. Catalyst shrinkage has been cited as a main reason why the radial-flow reactor is not as obvious a choice for methanol synthesis as for ammonia synthesis [56]. The methanol synthesis catalyst is mechanically much weaker than the ammonia synthesis catalyst, and it shrinks significantly during activation, which must take place in the reactor.

The flow direction across a radial-flow reactor can affect material selection for the catalyst screens and catalyst settling [57]. The design considered is for an ammonia synthesis reactor with the feed at 400 °C and the effluent at 510 °C. The diameter of the inner catalyst screen is approximately 90 cm, and the diameter of the outer screen 205 cm. For the outward-flow design, the inner screen is made of 2-1/4 Cr and 1 Mo and the outer screen 304 S.S. For the inward flow design, the inner screen is made of 304 S.S., and the outer screen 2-1/4 Cr and 1 Mo. Because it is rated for higher temperature service, 304 S.S. is selected for the screen where the effluent exits. Over the temperature range from 25 to 510 °C, the average thermal expansion coefficients of 304 S.S. and 2-1/4 Cr and 1 Mo are $18.4 \times 10^{-6}\ K^{-1}$ and $13.5 \times 10^{-6}\ K^{-1}$, respectively. The basket volume increases by 0.825 % for the inward-flow design and 1.966 % for the outward flow design, each time the reactor is heated from ambient temperature to its normal operating temperature. For this specific design, the outward-flow reactor will have more than twice as much catalyst settling as the inward-flow reactor, and will experience greater stress on the catalyst screens as it goes through the startup and shutdown cycles over its lifetime.

To monitor catalyst settling, a thermowell with multiple thermocouples can be inserted from the top to measure the temperature profile along the length of a radial-flow reactor. If the catalyst drops below the solid sections of the catalyst basket, the top thermocouple will measure a temperature much higher (endothermic reaction) or much lower (exothermic reaction) than the other thermocouples below.

The temperature profile also indicates if the reactant gas is distributed uniformly along the length of the catalyst bed. If it is, the temperature readings at different heights should be approximately the same.

Figure 6. Effect of reactor geometry on flow distribution a) Friction loss dominates; b) Effect of deceleration and acceleration dominates

Special design is required to allow the thermowell to grow against the surrounding catalyst. The increase in length due to thermal expansion can be very significant: for example, a 15 m long, 304 S.S. reactor grows 14 cm when it is heated from 25 to 540 °C. Some companies such as Gayesco specialize in providing thermowells and thermocouples for this type of reactor service.

Figure 7. Catalyst basket screen [53]

As illustrated in Figure 9, some flow may channel through the catalyst above the perforated section of the basket. In the extreme case, the upward vapor flow fluidizes the catalyst, and the catalyst fines generated from fluidization penetrate into the catalyst bed and the downstream screens, resulting in a significantly

greater pressure drop across the reactor. The catalyst loaded above the perforated section should be sufficient to allow for settling and to prevent channeling. In some radial-flow reactors, a baffle plate is mounted above the perforation to further restrict the channeling.

Figure 8. Radial (P_r) and tangential (P_t) pressures on the inner and outer screens of an ammonia converter after catalyst loading [52]

Figure 9. Top section of a radial-flow reactor

Ref. [14] describes experiences at two 1850 t/d ammonia plants that were forced to shut down because of excessively high pressure drops across the reactors, and how the designs of the reactors were modified to solve the pressure drop problems. Both plants use Kellog Brown & Root's Advanced Ammonia Process (KAAP) technology, which has four radial catalyst beds in the reactors. The first bed, packed with iron catalyst, is of the conventional design with no reactant flowing through the settling zone (called freeboard zone in [14]). The lower three beds, which are packed with high-activity, precious metal based catalyst, have a KAAP patented design that is composed of three major sections: freeboard, chute, and main bed (see Fig. 10). The reactant is directed to pass through the freeboard zone first before it reaches the main bed. The chute is the conduit whereby the catalyst moves from the freeboard zone into the main bed as settling occurs. This unique design allows 100 % utilization of all catalyst loaded. The freeboard section is subdivided into two parts: a freeboard catalyst zone and a freeboard bypass zone. A portion of the feed gas passes through the catalyst zone, mixes with the balance of the feed gas from the bypass zone, and the combined gas stream then flows to the main bed. Initially a screen was placed between the freeboard catalyst zone and the freeboard bypass zone. After some investigations with CFD modeling and a cold mock-up test unit, it was discovered that there was enough upflow from the catalyst zone to the bypass zone to fluidize the catalyst, and the catalyst particles pushed through the gaps between the screen panels plugged the inlet screens of the main bed, causing the pressure drop to increase. At one plant, the screen between the freeboard bypass zone and the freeboard catalyst zone was replaced with a solid plate. At the other plant, the opening at the outlet of the freeboard bypass zone was blanked, forcing the gas to flow downward through the catalyst zone. Both modifications stopped the increase in reactor pressure drop.

Figure 10. KAAP reactor catalyst bed [14]

To utilize the catalyst reserved for settling (15 % of the total loading), Axens, a subsidiary of IFP, developed the Texicap design: a flexible flow guide that settles with the catalyst to prevent bypass across the gap above the catalyst bed [58]. For a similar purpose, Ammonia Casale developed the axial-radial flow bed design, which allows about 90 % of the feed gas to pass through the catalyst bed in a radial direction and the balance to pass down through a top layer of catalyst in an axial direction (see Fig. 11). In addition to ammonia synthesis, Ammonia Casale has applied this design to the high-temperature CO shift reaction for the revamp of an ammonia plant [59]. It claimed that the water droplets leaking from an upstream steam generator forms a layer of cake preferentially on top of the axial bed, shifting more gas flow toward the radial catalyst bed and minimizing the effect on the total reactor pressure drop.

7. Acknowledgments

The author first started his study of radial-flow packed-bed reactors while he was a graduate student at the University of Washington. He would like to express his appreciations to Professor Bruce A. Finlayson for suggesting radial-flow reactor as the subject of his Ph.D. thesis and to the Department of Chemical Engineering at the University of Washington for the financial aids that supported his graduate study. The author would also like to thank Sanjeev Ram of ABB Lummus for his valuable comments on this paper.
